Actin filaments in the axon are short (1 μm) compared to the length of microtubules (Fath & Lasek, 1988), and they too have an intrinsic polarity due to the identical orientation of the actin subunits that make up the filaments. The terms *plus end* and *minus end* are used to distinguish the two ends of the actin filaments. The two ends of actin filament are sometimes referred to as *barbed* (plus) and *pointed* (minus) ends like the two ends of an arrow. Actin filaments form a cross-linked network near the cell membrane (the cell cortex). The plus ends of some actin filaments are attached to the plasma membrane. The molecular motors that transport vesicles on actin filaments are part of a large superfamily of myosins. Most myosins are plus end-directed motors and therefore move vesicles toward the plus ends of actin filaments.

Vesicles move over long distances in the axon on microtubules and transition onto actin filaments provides short-range movement in the cell cortex (Langford & Molyneaux, 1998). Therefore short-range movement functions to localize vesicles to membrane sites for capture, docking and fusion with the plasma membrane (DePina & Langford, 1999). Examples of vesicles that move on actin filaments are synaptic vesicles at the presynaptic terminal of the axon (Prekeris & Terrian, 1997) and smooth ER vesicles within the spines of neuronal dendrites and along the axon membrane (Dekker-Ohno et al., 1997; Tabb, Molyneaux, Cohen, Kuznetsov, & Langford, 1998). The class of myosin shown to transport endoplasmic reticulum (ER) vesicles in the squid giant axon (Tabb et al., 1998), synaptic vesicles in the axon terminal (Prekeris & Terrian, 1997), and ER in the spines of Purkinje cell dendrites (Dekker-Ohno et al., 1996; Takagishi et al., 1996) is myosin-V. Recent studies have shown that myosin-V interacts with kinesin, a microtubule-based motor. The functional significance of the interactions between kinesin and myosin-V has not been established. However, one plausible hypothesis is that interactions between these motors provide feedback and thereby allow coordination of motor activity during the transition of vesicles from microtubules to actin filaments. Such feedback between motors could explain the seamless transition of vesicles from microtubules to actin filaments observed in squid neurons. Therefore the direct interaction of motors from both filament systems may represent the mechanism by which the transition of vesicles from microtubules to actin filaments is regulated during fast axonal/dendritic transport.

FECHNER'S LAW

Gustav T. Fechner (1801–1887), professor of physics at the University of Leipzig, sought to measure the mind quantitatively. In approaching this task he studied stimuli and the sensations they aroused. His interest was in ascertaining how sensations changed with changing stimulation. While lying in bed on the morning of October 22, 1850, he conceived the essential idea of what was later to be called Fechner's law. In his subsequent derivation of the law (which appears at the beginning of the second volume of *Elemente der Psychophysik*), he began with Weber's law (that the just noticeable difference in stimulation is a constant proportion of the stimulus magnitude, or $JND = kI$) and the assumption that the sensation (R) of a stimulus is the cumulative sum of equal sensation increments. Translating this into differential form, he started with $dR = dI/I$ and integrated, under the assumption that $R = 0$ at absolute threshold (I_0), to get the equation $R = c \log(I/I_0)$. This equation is Fechner's law, where R is the sensation magnitude, c is a constant (which depends on the logarithmic base and

the Weber ratio), I is the stimulus intensity, and I_0 is the absolute threshold intensity. The law states that sensations follow a negatively accelerated increasing (logarithmic) curve. For example, the increase in brightness experienced in going from 1 to 10 lamps would be the same as the increase in brightness in going from 10 to 100 lamps. This is a special case of the general relationship, algebraically derivable from his law, that the stimulus magnitude (I_b) required to generate a sensation midway in magnitude to those sensations generated by stimuli of magnitudes I_a and I_c is exactly equal to the square root of the product of I_a and I_c (i.e., the geometric mean). Sensation magnitudes increase arithmetically when stimulus magnitudes increase geometrically.

In order to work with his formulation Fechner needed to know the value of the absolute threshold, I_0. In the first volume of his *Elemente der Psychophysik* Fechner describes methods for measuring differential sensitivity to stimuli (and later suggests their application to absolute sensitivity). These are the classical psychophysical methods that have been used by psychologists and others to determine thresholds (absolute and difference) for the various senses. They have also been used (with modifications) for clinical assessment of hearing, vision, and (to a limited extent) other senses. Fechner's law influences everyday life through applications in acoustics. A standard measure of sound is the sound pressure level (SPL) scale defined by the (Fechnerian) equation $SPL = 20 \log (P/P_0)$, where P is the pressure of the sound being measured and P_0 is the absolute threshold pressure. The volume control used in radio and television receivers (among other audio devices) is a variable resistor that has a logarithmic (or approximately logarithmic) variation in resistance in order to provide a positively accelerating audio amplitude output to counteract the negatively accelerated sensation response specified by Fechner's law, thereby resulting in a fairly even increase in loudness as the amplitude is increased by adjusting the volume control.

FEMALE SEX THERAPY

Sex therapy starts with the correct diagnosis of the sexual dysfunction presented by the patient. This is not an easy task considering the vague diagnoses provided by the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV;* American Psychiatric Association, 2000), the high comorbidity of sexual dysfunctions, and the lack of age-related norms for the female sexual response. The common agreement is to look at medical etiology of the sexual complaints and then to follow with the investigation of personal and relational aspects. After this initial phase, the most liberal therapists discuss potential goals and patient's expectations, which are not limited to sexual intercourse but could include skills such as communication and assertiveness, or feelings of enjoyment and comfort during sexual behaviors. The techniques used in sex therapy vary according to treatment goals, dysfunction, and patient characteristics. Because sex therapy is a symptom-oriented approach, much of the rational is borrowed from the cognitive-behavioral school. In order to select the most appropriate form of sex therapy and therapy goals, patient characteristics such as age, sexual orientation, ethnic background, and cultural expectations need to be considered.

Sexual Desire Disorders

Hypoactive Sexual Desire Disorder

Women with hypoactive sexual desire disorder (HSDD) complain of a low interest in general sexual activities. There are currently no empirically validated treatments for HSDD. Sex therapy techniques generally consist of 15 to 45 sessions of cognitive therapy aimed at restructuring thoughts or beliefs that may adversely impact sexual desire (e.g., "women should not initiate sexual activities," "sex is dirty") and addressing negative underlying relationship issues. Behavioral approaches are utilized to teach patients to express intimacy and affection in both nonsexual (e.g., holding hands, hugging) and sexual ways, to incorporate new techniques into their sexual repertoire that may enhance their sexual pleasure, and to increase sexual communication. Testosterone is effective in restoring sexual desire in women with abnormally low testosterone levels (e.g., secondary to removal of the adrenal glands, bilateral removal of the ovaries, menopause).

Sexual Aversion Disorder

Defined as the avoidance of sexual genital contact with a partner, sexual aversion disorder (SAD) has a high comorbidity with history of sexual abuse, vaginismus, and dyspareunia. Treatment for this condition often combines couples and cognitive therapy and focuses on solving the couple's conflict areas, emotional differences, and issues of

control. Anxiety reduction techniques such as systematic desensitization are used when the aversion is accompanied by strong feelings of anxiety. Systematic desensitization consists of identifying a hierarchy of sexual activities that provoke anxiety and then pairing relaxation techniques with imagining the sexual activity. The goal is for the patient to feel relaxed while imagining each sexual activity and eventually while actually engaging in each sexual activity. Some therapists feel that, when treating sexual abuse survivors, trauma-related issues need to be resolved before addressing SAD.

Arousal Disorders

Female Sexual Arousal Disorder

Female sexual arousal disorder (FSAD) is operationalized as the difficulty in reaching and maintaining vaginal lubrication or genital swelling until the completion of the sexual activity (ApA, 2000). Recently, theorists have argued that diagnosis of FSAD should consider not only the physiological dimension of sexual arousal (i.e., lubrication) but the psychological experience as well. Women of all ages may experience difficulty lubricating, although it tends to be more of a problem in later life, typically after menopause. Female sexual arousal disorder is generally assessed and treated in conjunction with female orgasmic disorder or HSDD. To date, there are no validated treatments that focus exclusively on treating female arousal problems, although a number of pharmacological agents for enhancing vaginal engorgement and lubrication are currently under investigation. Techniques are often employed to help the patient become aware of her anxiety or her sexual turn-off thoughts, emotions, or behaviors. To help facilitate arousal, the patient is sometimes trained in the development of sexual fantasies, communication skills, sexual assertiveness, sensate focus, and the use of erotica or vibrators. Lubricants such as KY Jelly or Astroglide are often recommended to help compensate for decreased lubrication. Recently, the Federal Drug Administration approved a hand-held battery-operated device called EROS-CTD for the treatment of FSAD. This suction device is placed over the clitoral tissue and draws blood into the genital tissue.

Orgasm Disorders

Female Orgasmic Disorder

Female orgasmic disorder (FOD) is defined in the *DSM-IV* (ApA, 2000) as the delay or absence of orgasm following a normal sexual excitement phase. The cognitive-behavioral treatment approach has received the greatest amount of empirical support for treating FOD. Reported success rates range between 88% and 90%. This therapy technique aims at reducing anxiety-producing thoughts associated with sexual activities and increasing positive behavioral experiences. The treatment is moderately short, averaging 10 to 20 sessions. The major treatment components include sensate focus, directed masturbation, and systematic desensitization. Sensate focus involves exchanging physical caresses, moving from nonsexual to increasingly sexual touching of one another's body over an assigned period of time. Directed masturbation involves a series of at-home exercises that begin with visual and tactile total body exploration and move toward increased genital stimulation with the eventual optional use of a vibrator. Directed masturbation is the technique with the best success rates; systematic desensitization is particularly useful when anxiety plays a primary role in the dysfunction. Couples therapy that focuses on enhancing intimacy and increasing communication has also been used for the treatment of FOD, but the success rates of this approach have not been well established.

Sexual Pain Disorders

Dyspareunia

Dyspareunia refers to genital pain associated with intercourse (APA, 2000). Vulvar vestibulitis is the most common type of premenopausal dyspareunia, whereas vulvar or vaginal atrophy is mostly reported by postmenopausal women. Women with these types of dyspareunia complain of pain in the vulvar area or anterior portion of the vagina upon penetration. The assessment of the type of dyspareunia should include information on the location, quality, intensity, time course, and meaning of the pain. The few studies that have examined treatment efficacy showed a moderate success rate of cognitive-behavioral techniques and biofeedback. The cognitive-behavioral approach includes education and information about dyspareunia, training in progressive muscle relaxation and abdominal breathing, Kegel exercises to train the patient to identify vaginal tenseness and relaxation, use of vaginal dilators, distraction techniques to direct the patient's focus away from pain cues, communication training, and cognitive restructuring of negative thoughts. During biofeedback, the patient is instructed to contract and relax her vaginal muscles while a surface electromyographic sensor inserted in her vagina provides her with feedback on muscular tenseness.

Vaginismus

Vaginismus is the involuntary contraction of the outer third of the vagina, which impedes penetration of fingers, tampons, or penis. Sex therapy for vaginismus often consists of a form of systematic desensitization that involves instructing the woman to insert graded vaginal dilators into her vagina. The woman's control over the insertion of the dila-

tors is an important aspect of the therapy. The role of the partner in the exercise is passive if present at all. The emotional and psychological aspects of vaginismus are approached through patient education and control. Exercises that reduce anxiety and replace anxiety-provoking thoughts with positive sexual thoughts are sometimes used in conjunction with the behavioral techniques.

FEMALE SEXUAL DYSFUNCTION

Dysfunctions in female sexuality may occur in each phase of the sexual response cycle: desire, arousal, and orgasm or resolution. In addition, there may be pain or muscle spasm that prevents penile penetration or enjoyment of coitus. All can occur at random, during specific situations, or as a primary dysfunction in which the disorder has always been present.

Sexual dysfunctions in females, as in males, may stem from anxiety. Helen S. Kaplan described the causes as either current or remote. Current or ongoing causes occur during the sexual experience and create distraction, fear, anger, or other unpleasant emotional states; these interfere with the ability to relax and allow sexual arousal to build. Such immediate causes might include fear of failure, performance anxiety, lack of effective sexual technique, failure to communicate desires, or *spectatoring*—a term coined by William Masters and Virginia Johnson to describe conscious monitoring and judging of sexual behavior. Remote causes are derived from previous childhood experiences, intrapsychic conflict, and/or serious problems within the relationship between sexual partners. Guilt about past sexual experiences, extremely restrictive family and religious backgrounds, a history of traumatic sexual experiences such as incest or sexual assault, or unconscious conflicts that evoke anxiety at the time of sexual encounters may result in maladaptive sexual functioning. Because sexual activities are more discouraged for females in Western cultures, there may be more difficulties in sexual functioning for adult women than for men. When the sexual disorder is absolute and arousal or orgasm has never occurred, remote causes are highly suspect in etiology. Current factors creating anxiety are more typically responsible for random or situational dysfunctions.

Relationship variables are frequent etiological factors. Communication problems, anger, lack of attraction to or love for the partner, power struggles, and lack of trust and respect create rejection, hostility, and distance between sexual partners. This impairs the woman's ability to abandon herself to sexual pleasure.

Disorders of Desire

Disorders of desire were identified later than were other dysfunctions, when the scope of sexual performance was expanded to include the preliminary emotional and physical reactions of arousal and desire. Kaplan states that inhibited or hypoactive sexual desire may be the most common, sexual dysfunction.

Inhibited sexual desire (ISD) is referred to in the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (*DMS-IV*) as a "persistent and pervasive inhibition of sexual desire" (i.e., the woman experiences low libido, lack of sexual response to genital stimulation, and lack of or very limited interest in and satisfaction with sexual activities). Women may react to this dysfunction with any of a wide range of emotions, from nonchalant acceptance to worry and acute distress. Sexual dysfunction is diagnosed when the individual experiences distress with the symptom. Absolute or primary inhibited desire is rare; situational ISD is more common.

Orgasmic Dysfunction

Orgasmic dysfunction is present when the female has great difficulty in experiencing orgasm or is unable to do so with effective sexual stimulation. Adequate desire and physiological and emotional arousal may be present, but anxiety interrupts the arousal buildup prior to the orgasmic relief.

Controversy reigned for many years about the types of female orgasm and the desirability of each. Vaginal and clitoral orgasms were alleged before the work of Masters and Johnson in 1966. With laboratory data, they concluded that all orgasms are essentially similar and consist of sensory input from the clitoris and muscle contractions by the vagina. Conclusive data do not exist concerning the incidence of women who have orgasms during coitus without concurrent clitoral stimulation, although estimates range from 30 to 50%.

Vaginismus

Vaginismus is an involuntary spasm of the vaginal muscles that prevents penile penetration. Arousal and orgasm may be present, but penetration is impossible. This spasm is a conditioned response to the anticipation of pain with intercourse; phobic avoidance of intercourse is often present. Etiology may include incidents of rape, painful attempts at coitus, vaginal and pelvic conditions that engender pain with sexual contact (vaginal infections, endometriosis,

pelvic inflammatory disease), or misinformation or ignorance about sex. Vaginismus is a major factor in unconsummated marriages and is accompanied by fantasies of physical injury and pain. Gradual dilation of the vagina in a short time span (a few days) can often eliminate the muscle spasm and allow for penetration.

Dyspareunia

Dyspareunia is similar to vaginismus in that there is pain associated with sexual intercourse; however, the involuntary vaginal muscle spasm is absent. Dyspareunia may be caused by insufficient vaginal lubrication due to lack of sexual arousal, senile vaginitis, or reactions to medication. It may also result from gynecological disorders such as herpes, vaginal infection, endometriosis, rigid hymen, or hymeneal tags. When pain accompanies intercourse, anxiety results, arousal diminishes, and there is avoidance of sexual encounter. Complete physical and pelvic examinations are required in the assessment and treatment of dyspareunia because of the many physical factors that could contribute to the pain.

Sexual dysfunction typically is treated with some form of sex therapy. Often this is brief, behaviorally focused therapy that aims at symptom removal. Barriers to effective sexual functioning are identified, and a combination of communication and sensual touching assignments are given.

FETAL ALCOHOL SYNDROME: BACKGROUND, TREATMENT, AND PREVENTION

Historical Background

Suggested adverse effects of maternal drinking appeared in seventeenth-century England, and several observers reported that mothers who drank heavily during the early eighteenth-century “gin epidemic” had children who were small, sickly, and mentally slow. In the nineteenth-century, reports linked stillbirth, infant mortality, and mental retardation to maternal drinking during pregnancy. However, claims of ancient descriptions of damaging effects of maternal alcohol consumption appear to be erroneous (Abel, 1984).

Formal studies in the early 1900s failed to find adverse effects of maternal drinking. Montagu’s conclusion seemed well founded in 1965: “[I]t now can be stated categorically . . . that no matter how great the amount of alcohol taken by the mother . . . neither the germ cells nor the development of the child will be affected” (p. 114). However, Lemoine, Harousseau, Borteryu, and Menuet (1968) reported abnormalities in the three areas now associated with fetal alcohol syndrome (growth retardation, low intelligence, and facial anomalies) in children of alcoholic parents, and in 1973 fetal alcohol syndrome (FAS) was named and thoroughly described (e.g., Jones, Smith, Ulleland, & Streissguth, 1973).

Incidence and Risk Factors

Incidence of FAS is approximately 1 in 1,000 live births worldwide and many times higher in the United States (Abel, 1998). Estimates vary widely across study and country, reflecting national or regional differences, sampling errors, and differing diagnostic criteria. Combined incidence of FAS and less severe fetal alcohol effects (FAE) or alcohol-related neurodevelopmental disorder (ARND) may be 9 in 1,000 births (Sampson et al., 1997).

Full FAS apparently occurs only with heavy maternal drinking, and incidence and degree of FAE/ARND increases with amount of prenatal maternal alcohol consumption (e.g., Abel, 1998). Animal experiments confirm that the damage is from prenatal alcohol and not secondary to another factor (e.g., Abel, 1998; Sampson et al., 1997). Although some (e.g., Abel, 1998) claim that prenatal alcohol exposure has a threshold effect, considerable research suggests that many effects show a continuous dose-response relationship (e.g., Sampson et al., 1997). Indeed, alcohol-exposed children without characteristic FAS features show significant deficits in IQ relative to normal children (Mattson & Riley, 1998).

FAS occurs much more commonly in offspring of mothers of lower socioeconomic status (SES) even after equating alcohol intake in different SES women (Abel & Hannigan, 1995). Binge drinking is a particularly high risk factor; other factors include minority ethnic status, smoking, maternal age, and undernutrition (e.g., Abel, 1998; Abel & Hannigan, 1995).

Genetic factors in both offspring and mothers also play a role. Fraternal twins of alcoholic mothers show differential development and performance (e.g., Streissguth, 1986). Pregnant mice from two different strains given comparable doses of alcohol had different blood-alcohol levels, and offspring of the higher-level strain had more anomalies, implicating maternal factors (Chernoff, 1980).

FAS Effects from Childhood to Adulthood

FAS effects persist into adulthood (e.g., Streissguth et al., 1991). FAS/FAE adolescents and adults average about 2 standard deviations below the mean in height and head circumference. Mean IQ is in the mildly retarded range, but variability is high. Those with the most severe physical symptoms in childhood have the lowest later IQ scores. The characteristic low weight of FAS/FAE children largely disappears. FAS facial dysmorphologies become less distinctive with age, although features such as short palpebral fissure length remain. Only a few affected children or adoles-

cents can cope in regular classes without special help; many are in self-contained special education classes. Although academic deficits are broad, arithmetic deficits are particularly large. Many adults are not employed and are in sheltered workshops or institutions.

Children and adolescents with FAS/FAE, even those without mental retardation, show behavioral deficits and excesses that present serious management challenges (e.g., Carmichael Olson & Burgess, 1997; Mattson & Riley, 1998). Common features include hyperactivity, inattention, impaired learning of verbal material, receptive and expressive language problems, difficulty conforming to social norms, and fine motor deficits. Temper tantrums in younger children and serious conduct disorders in older ones are a particular concern. Streissguth and Kanter (1997) described "secondary characteristics" that intervention might reduce and "protective factors" that reduce the those characteristics. The secondary factors are serious mental health problems; disrupted school experience; trouble with the law; inpatient or prison confinement for mental health, substance abuse, or crime problems; inappropriate sexual behavior; and alcohol or drug problems. Protective factors are a stable and nurturant home, particularly from 8 to 12 years of age; diagnosis before age 6; not having been abused; staying in living situations for extensive periods; diagnosis of FAS rather than FAE (apparently paradoxically, lower IQ was associated with fewer secondary characteristics); and having basic needs met for at least 13% of life.

Treatment

Early intervention may reduce some behavioral problems. Pharmacological and behavioral interventions have had varied success (e.g., Carmichael Olson & Burgess, 1997; Streissguth & Kanter, 1997). A highly structured and relatively low-stimulating environment improves attention and reduces problem behavior in both adults and children (e.g., Carmichael Olson & Burgess, 1997). The high level of Attention-Deficit/Hyperactivity Disorder in FAS/FAE individuals suggests that stimulant medication would be effective, but one study found highly variable response to stimulants: Generally, medication reduced hyperactivity but did not increase attention (Snyder, Nason, Snyder, & Block, 1997). Given the variety and extent of problems manifested by FAS/FAE individuals and the effect of these problems on others, Clarren and Astley (1997) suggest that clinics specifically devoted to FAS/FAE individuals may be needed.

Prevention

Although FAS is completely preventable theoretically, alcohol abuse is resistant to treatment, and relapse rates are high. Education programs may lower consumption by moderately drinking women during pregnancy but are unlikely to affect alcohol-abusing women, whose infants are most at risk. Treatment and prevention programs targeted specifically at alcohol-abusing women (e.g., Kilbey & Asghar, 1992; National Institute on Alcohol Abuse and Alcoholism, 1987) may be necessary to decrease the incidence.

University of North Carolina, Wilmington

FETAL ALCOHOL SYNDROME: DIAGNOSIS AND DESCRIPTION

Fetal alcohol syndrome (FAS) is a complex of physical anomalies and neurobehavioral deficits that may affect offspring of heavy-drinking mothers. First described in 1973 (e.g., Jones, Smith, Ulleland, & Streissguth), FAS is the most prevalent environmental and preventable type of mental retardation in the Western world. Prenatal exposure to alcohol has a continuum of effects: less serious ones, termed *fetal alcohol effects* (FAE), and alcohol-related neurodevelopmental disorder (ARND) among others (see Table 1).

Diagnosis, which is based on clinical signs and family history, may be difficult. Diagnostic criteria themselves are controversial. Even offspring of mothers who drank heavily during pregnancy show widely varying and nonunique effects, and numerous lifelong behavior problems may develop in those with minimal physical signs (e.g., Sampson, Streissguth, Bookstein, & Barr, 2000). Full FAS is associated with three major effects, "the triad of the FAS" (Rosett & Weiner, 1984, p. 43):

1. Prenatal and/or postnatal growth retardation below 10th percentile, corrected for gestational age. Although it is generally viewed as FAS's most common characteristic, some suggest that growth retardation may not be either a primary or a defining characteristic (Carmichael Olson & Burgess, 1997).

2. Central nervous system (CNS) dysfunction (neurological abnormality, developmental delay, or mental impairment < 10th percentile). Mental retardation or subnormality is the most common indicator. Variability of IQ is high, with average IQ estimated at about 65 (Mattson & Riley, 1998). Children with the most severe morphology and growth indicators have the most severe intellectual and other CNS deficits. Prenatal alcohol has many adverse effects on the developing CNS (e.g., Abel, 1998; Stratton, Howe, & Battaglia, 1996). Affected infants and children may show failure to thrive, poor sucking, retarded speech/motor development, repetitive self-stimulating behaviors, auditory deficits, Attention-Deficit/Hyperactivity Disorder, oppositional defiant and conduct disorders, and seizures. Many of the behavior deficits and excesses reflect deficits in rule-governed behavior suggestive of impaired frontal-lobe functioning (Sampson et al., 2000).

3. Characteristic facies (at least two of three facial dysmorphologies: microcephaly [head circumference < 3rd percentile]; microphthalmia and/or short palpebral fissures; or

Table 1. Summary of IOM's (1997) Diagnostic Criteria for Fetal Alcohol Syndrome (FAS) and Alcohol-Related Effects

I. Category 1: FAS with confirmed maternal alcohol exposure
   A. Confirmed maternal alcohol exposure
   B. Characteristic pattern of facial anomalies such as short palpebral fissures and abnormalities in the premaxillary zone (e.g., flat upper lip, flattened philtrum, and flat midface)
   C. Growth retardation as indicated by at least one of the following: low birth weight for gestational age; decelerating weight over time not due to nutrition; disproportional low weight to height
   D. CNS neurodevelopmental abnormalities, including at least one of the following: decreased cranial size at birth; structural brain abnormalities (e.g., microcephaly, partial or complete agenesis of the corpus callosum, cerebellar hypoplasia); neurological hard or soft signs (as age appropriate), such as impaired fine motor skills, neurosensory hearing loss, poor tandem gait, poor eye-hand coordination

II. Category 2: FAS without confirmed maternal alcohol exposure
   A. Characteristic pattern of facial anomalies
   B. Growth retardation
   C. CNS neurodevelopmental abnormalities as in Category 1.

III. Category 3: Partial FAS with confirmed maternal alcohol exposure
   A. Confirmed maternal alcohol exposure
   B. Some components of characteristic pattern of facial anomalies as in Category 1.
   C. Growth retardation and CNS neurodevelopmental abnormalities, as in Category 1, or complex pattern of behavior or cognitive abnormalities that is inconsistent with developmental level and cannot be explained by familial background or environment alone, such as learning difficulties; deficits in school performance; poor impulse control; problems in social perception; deficits in higher-level receptive and expressive language; poor capacity for abstraction or metacognition; specific deficits in mathematical skills; or problems in memory, attention, or judgment

IV. Category 4: Alcohol-related effects
   A. Alcohol-related birth defects (ARBD): Presence of a subset of an extensive list of congenital anomalies, including cardiac, skeletal, renal, ocular, auditory, and numerous other malformations and dysplasias
   B. Alcohol-related neurodevelopmental disorder (ARND): Presence of any one CNS neurodevelopmental abnormality as described in Category 1 and/or the complex pattern of behavior or cognitive abnormalities, as in Category 3

poorly developed philtrum, thin upper lip, and flattening of the maxillary area). According to the Institute of Medicine (IOM), "At present, the facial features observed in FAS remain the most unique feature. . . . No one can receive an FAS diagnosis without an experienced clinician's assertion that the face, *taken as a whole,* appears to be the FAS face" (Stratton et al., 1996, p. 72, italics in original).

The IOM (Stratton et al., 1996) proposed the diagnostic categories shown in Table 1, which have been largely adopted by the American Academy of Pediatrics (2000). However, the categories have been criticized for several reasons (e.g., Abel, 1998; Sampson et al., 2000): (1) The distinction between FAS and alcohol-related effects is questionable, owing to high overlap between them in neurobehavioral effects—indeed, similar IQ deficits occur in alcohol-exposed children with or without FAS physical features (Mattson & Riley, 1998); (2) prenatal alcohol exposure during only a narrow period leads to facial deformities, whereas exposure over a much wider range leads to CNS and consequential behavioral defects; (3) requiring a history of maternal drinking during pregnancy is problematic because women may underreport their drinking and adopted infants may have no maternal histories; thus, underdiagnosis is a concern. Researchers are attempting to identify clear biological markers of prenatal alcohol exposure. At this time, except in cases with clear and distinct infant features and a known history of maternal drinking during pregnancy, practitioners should consult with expert diagnosticians before making a diagnosis. Because milder phenotypes characteristic of FAS/FAE may result from problems other than alcohol (Streissguth, Sampson, Barr, Clarren, & Martin, 1986), pregnant women who occasionally drank small amounts of alcohol and have slightly deformed infants should not be made to feel that alcohol necessarily caused the deformities.

FIGHT/FLIGHT REACTION

Fighting and fleeing are the two basic responses available to most animals, including humans, when they are dealing with danger. A threat to the survival of an organism will be met with one or both of these behaviors. The threat may be real or perceived, and the response may be physical or, in the case of humans, abstract or intellectual. Further, the fight/flight response may be by an individual alone or by a group acting together.

A genetic basis for fight/flight behaviors shares an argument for the more general topic of aggression. That is, these behaviors have been prevalent throughout history; they are shown by almost all species of animals; they appear early in childhood; and they appear to be of some survival value. In contrast, learning is an important factor influencing aggressive acts.

W. R. Bion incorporated fight/flight behavior into an elaborate theory of human behavior. This theory has had great impact on the understanding of individuals' actions, especially as they occur in a social context. W. R. Bion and others such as Henry Ezriel brought greatly increased understanding of the relationship that exists between the basic biological drives in man, such as fear and anxiety, and other observed behaviors, both abnormal and normal.

FIVE-FACTOR MODEL OF PERSONALITY

Introduction

Personality traits describe individual differences in human beings' typical ways of perceiving, thinking, feeling, and behaving that are generally consistent over time and across situations. Beginning with the work of Allport and Odbert (1936), trait psychologists have attempted to identify a set of basic traits that adequately describe variation in human personality. This effort has employed two strategies, the analysis of descriptive adjectives across human languages (the lexical approach) and the measurement of various traits derived from personality theories (the questionnaire approach). For nearly 50 years competing sets of fundamental traits (e.g., by Cattell, Eysenck, and Guilford), typically derived through factor analysis, created disagreement about which traits were basic. However, in the 1980s, a convergence of the lexical and questionnaire strategies generated a consensus among many trait psychologists that five basic broad traits provided an adequate description of individual differences (McCrae & John, 1992). This set of basic traits is referred to as the Five-Factor Model of Personality (FFM).

Contemporary factor analytic investigations have recovered the FFM traits in diverse languages spoken around the world (McCrae & Costa, 1997) and demonstrated that most traits assessed by personality questionnaires, regardless of their original theoretical roots and applied purposes, can be subsumed by the FFM (McCrae, 1989). The major advantages of this consensus include the provision of a common language for psychologists of different traditions to use in describing individual differences, and the ability to focus research on the roles traits play in diverse human phenomena rather than on endless debates over which traits are basic (Wiggins, 1992).

Description

Although differences of opinion regarding the names of the five basic traits exist, I use the labels associated with the most popular articulation of the FFM (Costa & McCrae, 1992).

Neuroticism versus Emotional Stability. High neuroticism suggests a proneness to psychological distress and emotional reactivity, reflected in chronic experiences of anxiety, depression, self-consciousness, low self-esteem, and ineffective coping. Low neuroticism does not guarantee psychological health but does suggest a calm, even-tempered emotional style.

Extraversion versus Introversion. High extraversion suggests an interpersonal style marked by preferences for social interaction, high activity levels, and the capacity to experience positive emotions. Low extraversion suggests a preference for solitude and a reserved, quiet, and independent interpersonal style, but not an inherently unhappy or unfriendly individual.

Openness to Experience versus Closed to Experience. High openness suggests an active pursuit and appreciation of experiences for their own sake, reflecting curiosity, imagination, tolerance of diverse values and beliefs, novelty-seeking, and attraction to aesthetic experiences. Low openness suggests a preference for conventional attitudes, conservative tastes, dogmatic views, and little interest in the unfamiliar or markedly different.

Agreeableness versus Antagonism. High agreeableness suggests a friendly, cooperative, trustworthy, and nurturant interpersonal style. Low agreeableness suggests a cynical, rude, abrasive, suspicious, uncooperative, and irritable interpersonal style.

Conscientiousness versus Unconscientiousness. This trait describes individual differences in the degree of organization, persistence, control, and motivation in goal-directed behavior. High conscientiousness reflects a tendency to be organized, reliable, hard-working, self-directed, deliberate, ambitious, and persevering. Low conscientiousness reflects a tendency to be disorganized, aimless, lazy, careless, lax, negligent, and hedonistic.

Theory

Although it is empirically derived through factor analytic investigations of language and personality questionnaires, it is erroneous to conceive of the FFM as atheoretical. The emerging consensus led to the question "Why are these five basic traits universal descriptors of human individual differences?" Several theoretical viewpoints have been applied to this question (Wiggins, 1996), including the lexical hypothesis, the dyadic-interactional perspective, socioanalytic personality theory, evolutionary theory, and personality metatheory.

Assessment

The FFM can be assessed through self-reports, observer ratings, and a structured interview. Individuals interested in assessing the FFM should consider important differences among instruments and methods (Widiger & Trull, 1997).

Applications

The FFM has been widely applied in diverse domains of psychological science and practice. Clinical psychologists have demonstrated the advantages of using the FFM for treatment planning and understanding the psychotherapy process. The FFM has also been linked to both symptom-based psychopathologies and the personality disorders. Beyond clinical psychology, the FFM has been widely used in industrial/organizational psychology, cross-cultural psychology, health psychology, social psychology, developmen-

tal psychology, counseling, and close relationships. Finally, the FFM dimensions are likely to be reliable and valid predictors of many everyday behaviors of potential interest to investigators.

Criticisms

Although the FFM has been successfully applied in diverse areas of psychology, criticisms of the model have been raised (Block, 1995, McAdams, 1992; Westen, 1995). These largely focus on the inherent vulnerabilities of factor analysis, the lack of validity scales for most FFM inventories, and the limitations of the descriptive scope of the FFM.

FORENSIC PSYCHOLOGISTS: ROLES AND ACTIVITIES

Forensic psychology deals with the interface of psychology and the law, and with the application of psychology to legal issues. This specialty includes a wide range of clients and settings, including individuals of all ages, couples, groups, organizations and industries, government agencies, schools, universities, inpatient and outpatient mental health settings, and correctional institutions. Forensic psychologists may become involved in such diverse areas as criminal competency and responsibility, tort liability and/or damages, the effects of workplace discrimination or harassment, products liability, mental hospital commitment and treatment, divorce and custody litigation, risk assessment for future aggressive behavior, treatment of offenders, rights of patients and offenders, special education, eyewitness identification, the effect of suggestibility on children's testimony in cases of alleged child sex abuse, jury selection, police selection and training, workers' compensation, and professional liability. Events of recent years have led to increased attention to prediction of violence in the workplace and in schools. Although few forensic psychologists are qualified in all these areas, all are expected to have a basic knowledge of certain core areas as well as a thorough knowledge of their specialization.

Although psychiatry has had a role within the legal system for many years, it was not until Judge Bazelon's decision in *Jenkins v. United States* in 1962 that psychology obtained firm legal status. In *Jenkins,* a criminal case, the trial judge had ordered the jury to disregard the psychologist's testimony regarding mental disease. He did so on the basis that a psychologist is not qualified to give a medical opinion. The Court of Appeals ruled that the judge was in error and stated that "some psychologists are qualified to render expert testimony in the field of mental disorder." The court went on to suggest criteria for qualifying a psychologist as an expert. In the years since that decision, other cases and the Federal Rules of Evidence have substantially broadened the issues included within psychologists' legally defined expertise. Today, though there are some differences among states, and between the states and federal government, psychologists are regularly accorded expert status in practically every appropriate area of criminal, civil, family, and administrative law.

The growth of forensic psychology has been manifested in a variety of other ways. Some interdisciplinary programming between law schools and psychology departments began in the 1960s. The early 1970s witnessed the development of joint PhD-JD degree programs and psychology PhD programs with a specialty in forensic or correctional psychology. Today there are a substantial number of such programs, and also a growing trend within psychology graduate schools to include law-related courses in the curriculum.

A number of professional organizations have also emerged. In 1980 the American Psychological Association membership approved the creation of a Division of Psychology and Law (Division 41). The American Board of Forensic Psychology was established in 1978. Its purpose is to identify qualified practitioners to the public and to promote forensic psychology as a recognized discipline. Appli-

cants for diplomate status must, among other criteria, have at least 1,000 hours of experience in forensic psychology in a 5-year period in order to qualify. They then must submit a work sample, which, when approved, allows them to take a 3-hour oral peer-review examination.

Another manifestation of growth is the publication of journals and books specific to the field. Among the important journals are *Law and Human Behavior, Behavioral Science and the Law, The American Journal of Forensic Psychology,* and *Psychology, Public Policy and Law,* although many other journals also publish relevant articles. Among books that provide an overview of the field are Heilbrun, Marczyk, and DeMatteo's *Forensic Mental Health Assessment: A Casebook* (Oxford University Press, 2002) and Hess and Weiner's *The Handbook of Forensic Psychology* (Wiley, 1999). A further aspect of the growth of forensic psychology has been the development of specialized forensic instruments to assess issues such as criminal competency, criminal responsibility, and parenting capacity.

Specific Issues Addressed by Forensic Psychologists

In most forensic cases the questions that the psychologist is called upon to answer fall into three categories: (1) diagnostic questions: personality dynamics, presence of psychosis or organicity, evidence of malingering, and so on; (2) questions involving inference from the diagnostic level to opinions regarding specific legal questions, such as competency to stand trial, the relationship of a psychological disorder to an accident, the best interests of the child, and so forth; and (3) questions regarding disposition: need for treatment and prognosis with and without treatment, potential for future dangerous behavior, and the like. To address these questions, the forensic psychologist must not only possess the usual evaluation skills, but also be aware of special forensic instruments and relevant case law. Also, there will be important confidentiality/privilege issues, which will vary from situation to situation. The psychologist must be aware of these and take the necessary steps to protect clients. The psychologist must also work with attorneys prior to the evaluation to determine the question to be addressed and to help them understand what the evaluation can and cannot do. For example, an attorney may incorrectly request that the evaluation answer the question of whether the person is telling the truth regarding the commission of a crime. The attorney must also understand that the payment of a fee is for the evaluation only and that there is no commitment on the part of the psychologist to testify on behalf of the client. Whether testimony occurs depends on the findings of the evaluation.

It is also necessary for the psychologist to take a *forensic history,* which is more comprehensive than the usual history and is likely to include such information as hospital records, police reports, and statements of witness. These sources of information will then be referenced in the report based on the evaluation.

Testifying in Court

In some cases the report of the forensic psychologist will be accepted without an appearance in court. But at other times the psychologist may be called to testify. Giving testimony can be a traumatic experience: The key to minimizing difficulties is thorough preparation. This preparation takes place on several levels. The first level involves a thorough knowledge of the relevant law, the tests used, and the test findings. The psychologist must also be able to articulate findings without using excessive jargon and by utilizing behavioral examples that will illustrate the statements made. The second level of preparation involves meeting with the attorney. The forensic psychologist must abide by ethical principles and must retain personal integrity. However, the psychologist also has the responsibility to present the findings as effectively as possible. The attorney, on the other hand, is required to advance the client's interest. The attorney has been taught never to ask a witness a question to which the attorney does not already know the answer. Preparation, therefore, includes an agreement between the psychologist and the attorney on the order in which the findings will be presented, on what questions will be asked, and on what the psychologist's answers will be. It is also helpful to review likely cross-examination questions and for the psychologist to indicate what the answers would be.

The credibility of the psychologist in the courtroom will depend on several factors. The first of these is credentials: The psychologist should provide the attorney with a curriculum vitae, which the attorney can use when presenting the psychologist's qualifications. The credibility of the psychologist will also depend on courtroom demeanor. The psychologist on the witness stand must remember that the cross-examining attorney is only doing a job when questioning the credibility of the psychologist and of the findings. The cross-examination is not a personal attack, although if one loses perspective, it is easy to feel personally attacked. In giving testimony, the psychologist should not hesitate to say that he or she did not understand the question or does not know the answer, or that there is insufficient information to answer the question.

Forensic Treatment

Forensic treatment covers as wide a range of cases as forensic evaluation. In criminal cases, treatment may consist of therapy focused on returning an incompetent individual to competency. Or it may provide emotional support to the person who must face imprisonment. Treatment in criminal cases sometimes includes therapy focused on personality problems or on aggressive or sexual behavior while the individual is incarcerated, or outpatient therapy as a condition of probation or parole. Treatment of offenders requires special knowledge about the criminal justice system, the nature and effects of the prison environment, the probation-parole system, and the personality characteristics and/or

behavior frequently observed in offenders. Group therapy or behavioral therapy techniques are often valuable in treating sexual offenders, offenders with alcohol problems, and others.

In a civil damage situation, treatment may consist of insight-oriented or supportive psychotherapy. In addition, special methods such as behavior therapy, cognitive therapy, or biofeedback may be used for pain management or to treat anxiety or depression. The therapist must be aware that testimony may be required in court, and this may at times influence both the mental status of the client and the course of therapy. Often in such cases the therapist may find the legal situation to be at odds with the therapeutic situation. For example, it is often therapeutic for a patient who has been unable to work to return to work as soon as possible. However, this is often inconsistent with the approach being taken by the attorney. In such cases, the therapist has a responsibility to make the patient and the attorney aware of the recommendations, but the final decision as to whether to proceed on those recommendations lies with the patient.

In the child custody situation, treatment is often ordered by the court either to avoid full custody litigation or as part of the resolution of the conflict. The focus of treatment is to help the child make a positive adjustment, and this of course requires treatment of the child. However, treatment of the parents is almost always required as well. The treatment of the parents focuses on such issues as communication in dealing with the child, unconscious or conscious derogation of the other parent to the child, and resolution of conflicts between the parents. Conflicts often arise over visitation issues, so that the child becomes the focal point of conflict between the parents. Resolving such issues often requires joint sessions with the parents, which, though often explosive, may be necessary and productive.

Research in Forensic Psychology

Many of the questions asked of the forensic psychologist require only description of the present status of an individual. But many other questions make an explicit or implicit request for a prediction of future behavior. For example, the answers to such questions as the probability of future dangerous behavior, the likely response to treatment, or the adjustment of a child under various possible alternative custodial situations require not only thorough clinical evaluations, but also a knowledge of relevant research. The research may often reveal that clinical lore is incorrect. On the other hand, the state of the art is such that it is often difficult to support a clinical opinion within the framework of available research findings. It is, therefore, incumbent on the forensic psychologist to be both the recipient and the provider of research on these questions. The psychologist may not be called upon to provide research support for clinically based opinions, but he or she should be prepared to do so if necessary. In other types of cases, such as those involving eyewitness identification, the primary basis on which opinions are offered is the research.

The forensic psychologist must keep abreast of new information which emerges from research. Such effort, along with up-to-date knowledge of the law and modifications of the law by new cases, provides a perspective that, when combined with a thorough clinical approach, allows the forensic psychologist to be of greatest services to the legal system.

FORENSIC PSYCHOLOGY

Forensic psychology refers to the burgeoning field in which psychology and law share interest. Called *psycho-legal studies, psychology and law,* or *criminal and legal psychology,* among other terms, forensic psychology encompasses three basic and overlapping areas of collaboration between psychology and law. They are psychology *in* the law, psychology *and* the law, and psychology *by* the law.

Psychology in the law refers to the way that psychology has been used by the law to solve problems. Traditionally, these problems include determining sanity; assessing competency in both civil court (e.g., assessing the ability to take of one's affairs, or providing child custody recommendations in divorce proceedings) and criminal matters (e.g., the ability to contribute to one's defense at trial); classifying prisoners' risks in determining level of custody; assessing whether educational and employment practices are discriminatory; determining disability; recommending probation and parole suitability; and providing criminal behavioral analysis. When people think about psychologists in forensic matters, they are typically considering how psychologists work in the law.

As forensic psychology has grown, novel application of psychological expertise have developed. For example, a cognitive psychologist's consultation and testimony would be most helpful in determining whether targeted consumers would be confused by a trademark or logo from a company that was similar to a well-recognized company. Would there be trademark infringement if a new company was named "Tidee Soap Flakes," possibly capitalizing on the trademark

of a more established company with a similar name? Also, experimental psychologists would be helpful in determining the optimal amount and complexity of information on a highway sign that drivers whizzing by could process without distraction. When signs are poorly done or badly placed, suits might arise in which the testimony of psychologists specializing in forensic human factors might be essential. Psychologists also assess community attitudes to determine whether a fair trial can be conducted regarding highly publicized and notorious events. Psychologists assist attorneys in the selection of jurors during voir dire and can conduct focus groups to see how a jury might consider different legal arguments when confronting facts of a case. These innovative applications of psychology are helping further the growth in this area of forensic psychology.

Psychology of the law is centered on research about legal issues and how the law functions. For example, psychologists have determined that the usual way of conducting lineups (that is, the simultaneous display of six people for an eyewitness to view) is inferior to the sequential lineup, in which the eyewitness makes an individual judgment about one person at a time before viewing the second, third, fourth, and so on. The sequential lineup results in fewer misidentifications of innocent people with no loss of accuracy in detecting guilty parties. Psychologists have also studied how people view privacy. Most people think that only the owner or renter can grant entry into a home and allow seizure of items police may want. However, the law allows that anyone in a home, including a worker painting the house or repairing a refrigerator, may grant entry and allow seizure of property. Interestingly, police typically view privacy not as the law regards it but as citizens think of it.

Psychology of the law involves studying the decision-making processes of litigants (e.g., should I sue, and should I settle?); criminals (e.g., what makes a target vulnerable?); victims (e.g., have I been the victim of a crime, and is it worth pressing charges?); police (e.g., should I ticket or arrest this person?); prosecutors (e.g., is this crime worth prosecuting?); judges and juries (e.g., determining liability in civil cases and guilt in criminal cases, setting awards or sentences); and corrections (e.g., what degree of security is needed for this convict, and when should parole be granted?). Recent innovative research includes examinations of how jury instructions affect awards in tort cases. If the results of this research are applied, then we may not need legislatures to reform tort law. Psychology of the law concerns applying behavioral research strategies to legal phenomena in order to increase the fairness and effectiveness of the administration of justice in our society.

Psychology by the law refers to the laws, statutes, regulations, and ordinances that affect the practice of psychology. The psychologist who teaches must be aware of organizational procedure for handling such matters as admitting students into a program in a nonbiased fashion; apprehending student cheaters and according them appropriate due process as the institution has set forth; and recruiting and treating research participants in ethically and legally appropriate ways. Recently, the privacy of research data has come under attack, so that psychologists conducting research need to know what they can or cannot promise in terms of confidentiality of data gathered in research. The psychologist in practice needs to know about licensing and about confidentiality and privilege, as well as understanding the limits of each of these (e.g., most states have mandatory child abuse reporting statutes and require warnings of a patient's homicidal threats if such threats present an imminent danger to an identifiable third party). Psychologists who hire other professional staff need to know about employment and personnel law, and if services are rendered to the public, the psychologists need to provide reasonable accommodations to people with disabilities.

Each of these three areas of forensic psychology has grown explosively in recent years. The growth in the subscriptions to psychology journals, the popularity of forensic psychology workshops, the development of forensic psychology graduate programs, the Diplomate in forensic psychology, the publication of such works as the second edition of *The Handbook of Forensic Psychology* (Hess and Weiner, 1999), and even television shows portraying forensic psychologists are signs of interest in this area.

FORM/SHAPE PERCEPTION

Form/shape perception refers to how figure (as distinct from its background) information is specified so that object recognition and shape matching are possible and object-oriented actions can be made accurately. It is difficult to distinguish form from shape as, generally speaking, the terms are used synonymously (henceforth we will use *shape* to refer to form and shape). Shape information is available from vision and touch, although most research has focused on shape perception in vision.

As shape can readily been seen in monochrome line drawings and silhouettes, shape can be established without reference to color, motion, or depth information. Consequently, most research on shape perception has concentrated on how shape can be computed from edge-based stimuli. However, it is important to know that shape can also be computed from patterns of motion (shape-from-motion) by using Gestalt principles such as common fate (Johansson, 1973). Given certain constraints, shape can

also be perceived from shadow (e.g., Ramachandran, 1988). Therefore, how we perceive shape in the real world will be determined from at least three sources of visual information: edge, movement, and shadow.

Cognitive Processes

Processes of shape representation are usually thought to operate in a bottom-up or data-driven fashion (e.g., Marr, 1982; Biederman, 1987). Particular attention has been given to understanding whether shapes are processed as global entities or broken down into parts and shape constancy. Although some have claimed that it is the global aspects of a shape that are important for understanding its structure (e.g., Cave & Kosslyn, 1993), most authors believe that shapes are usually described in terms of parts and the relationships between parts. Specifying what the constitute parts of shapes are has been a theoretical challenge. Some authors have suggested a role for stored primitives or templates (Marr, 1982; Biederman, 1987) and others that parts are computed online using physical properties of the image (Hoffman & Singh, 1997). The weight of evidence is currently in favor of the latter approach with segmentation between parts being made at boundary cusps. The rule describing the places where shapes are divided into parts is called the *minima rule* (see Hoffman & Richards, 1984).

The representations of three-dimensional shapes must exhibit constancy such that their perceived shapes do not change with viewpoint, and various schemes have been proposed to achieve this. For example, objects might be described with reference to their principle axes (e.g., Marr, 1982) or from information directly available in the image (e.g., Biederman, 1987).

Not all shape processing can be bottom-up: Recent studies have shown that object recognition affects figure-ground segmentation (e.g., Peterson & Gibson, 1991; Peterson, de Gelder, Rapcsak, Gerhardstein, & Bachoud-Levi, 2000) and the perception of ambiguous and incomplete figures (Rock, 1983). Therefore, top-down processes are also likely to be critical for shape perception. However, exactly what top-down information is used in shape perception and the mechanisms through which it is exploited remain unknown.

Neuropsychology of Shape Perception

Patients exhibiting failures to properly specify shape information are said to suffer from *apperceptive agnosia.* In such cases, sensory loss is either absent or unable to account for their perceptual loss. It is also critical that patients are shown to have retained stored knowledge of object form and function. The classic test of shape perception is the Efron test (Efron, 1968). In the Efron test, patients have to judge whether two orthogonally oriented rectangles, matched for overall flux (luminance and area), have the same or different dimensions. Failure on this test can only be because of an inability to compute shape information. The locus of brain damage usually considered sufficient to produce apperceptive agnosia is diffuse damage of parieto-occipital cortex of the right hemisphere (Bradshaw & Mattingley, 1995).

The failure to consciously perceive shape does not necessarily imply that shape is not computed. There is good evidence that the conscious experience of shape doubly dissociates from the ability to reach and grasp appropriately for objects. Patients with optic ataxia cannot reach and grasp objects but can report accurately the shape of a stimulus along with the shape's location, size, and orientation (Perenin & Vighetto, 1988), whereas patients with visual form agnosia cannot report accurately the shape, size, or orientation of an object. Nevertheless, they can reach and grasp for objects automatically and without error (Goodale, Milner, Jakobsen, & Carey 1991). Therefore, a failure to consciously perceive shape does not mean that it has not been processed.

Neuroanatomy of Shape Perception

The cortical loci responsible for shape analysis have also been studied using functional imaging. The critical design for such a study must ensure that shape analysis is isolated from feature processing and activation of semantic memory using a subtractive methodology (see Peterson, Fox, Snyder, & Raichle, 1990). In studies where these conditions have been met, the cortical areas activated only during shape analysis are on the inferolateral surface of the brain near the junction of occipital and temporal lobes in both right and left hemispheres (e.g., Kanwisher, Woods, Iacoboni, & Mazziotta, 1997).

In conclusion, shape perception refers to a complex set of processes through which two- and three-dimensional figures come to be represented in order that recognition, matching, and actions can be supported. These processes are mostly driven by bottom-up considerations such that part decomposition and shape constancy can be achieved. However, shape processing is affected by top-down factors, as evidenced by its role in figure-ground segmentation and the perception of ambiguous figures. Shape processing can break down following brain damage to posterior regions of the right hemisphere, and the awareness of shape can be lost, although shape processing can still allow accurate grasping of objects. Functional imaging studies concur with the studies of brain-damaged patients in highlighting the role of posterior cortex in shape perception but suggest a role for both right and left hemispheres.

FRAGILE X SYNDROME

Little known until a new technique facilitated identification in the 1980s, Fragile X, or fra(X), is the most common heritable cause of mental retardation (MR). Fra(X) owes to a weak site on the X chromosome, is sex-linked, and is largely responsible for higher prevalence of MR in males than females. Discovery of the responsible gene has led to replacement of cytogenetic tests with more effective and less expensive DNA ones, which identify affected individuals and carriers (Hagerman & Lampe, 1999). Prevalence estimates of full expression in males and females are about 1 in 4,000–6,250 and 1 in 8,000–12,500, respectively (Saul & Tarleton, 2000). Fra(X) may account for 5% of children receiving special education services for mental retardation. Individuals with MR of unknown cause are routinely screened for Fra(X).

History

Martin and Bell's (1943) description of a family with an X-linked inheritance MR pattern in males helped to explain the long-known higher incidence of males with MR. Lubs's (1969) description of the fragile-X site drew little interest until accurate diagnosis led to recognition of its frequency (e.g., Sutherland & Hecht, 1985). The family studied by Martin and Bell is now known to be affected by fra(X), and Martin-Bell and Fragile X syndromes are synonymous.

Genetics

Fra(X) is unusual genetically (see Meyer & Batshaw, 2002). In typical X-linked disorders, a carrier female expresses no characteristics of the disorder but passes the defective gene, on average, to half of her children. Males who inherit the defective gene express its effects, whereas females are unaffected carriers. In fra(X), carrier females may manifest some fra(X) characteristics, including impaired intelligence and learning disabilities, and about 20% of fra(X) males show no apparent effects but pass the defective chromosome on to their daughters, who may have affected sons.

The underlying mutated defective fragile-X MR (FMR1) gene interferes with a particular protein apparently important in brain development. Normally, the genetic code shows some repetition in three nucleotide base pairs (triplet repeats), which on many chromosomes may expand abnormally over generations into fragile sites. The fragile-X site (FRAXA) normally contains 6–50 repeats of the cytosine-guanine-guanine (CGG) triplet base pair sequence. Asymptomatic transmitting, or permutation, males and carrier females have 50–90 and 50–200 CGG repeats, respectively, and do not show a fragile X site. Premutations occur in about 1 in 500 males and 1 in 250 females. Premutations of more than 100 CGG repeats almost always expand into full (200–3,000 CGG repeats) mutations in the next generation. Males and females with full mutations have observable fragile-X sites and symptoms. All males and 50% of females show MR. However, fra(X) involves the phenomenon of genomic imprinting, in which the sex of the transmitting parent influences expression of a mutation. Daughters of pre- or full mutation males generally have only premutations and are asymptomatic, whereas sons and daughters of pre- or full mutation females have further expanded CGG repeats. Offspring of full mutation females will always have full mutations, and those of permutation females have increased likelihood full mutations.

Characteristics of Affected Individuals

Expressivity of fra(X) is highly variable and can only be summarized here. Detailed descriptions are in Hagerman & Lampe (1999), Meyer and Batshaw (2002), and Online Mendelian Inheritance in Man (OMIM, 2002). About two thirds of postpubertal males show a "clinical triad": (1) moderate-severe MR; (2) craniofacial features (large forehead, protruding chin, coarse facies, long face, macrocephaly, and elongated ears); and (3) large testes (e.g., Sutherland & Hecht, 1985). Females and prepubertal males are more variable. Most prepubertal males show overgrowth from birth, with head size, fontanel, and body measurements exceeding the 97th percentile, but less distinct macroorchidism and craniofacial features. Fra(X) children may also show hyperextensible joints, high arched palate, mitral valve prolapse (a form of heart murmur), flat feet, scoliosis, strabismus, and low muscle tonus. Female carriers, particularly those with subnormal intelligence, may also show facial features, including high broad forehead and long face, and hyperextensibility.

Approximately 95% of affected males have mild to profound MR and some form of communication disorder. Affected males have particular difficulty with processing and short-term memory of serial information. Auditory memory and reception are poor. General language development is delayed relative to intelligence, and specific problems such as perseverations, repetitions, echolalia, cluttered speech, and dysfluencies are often shown. Many fully affected males show an apparently unique complex of behaviors, including stereotypies, particularly hand flapping, gaze aversion, avoidance of touch, hyperactivity, inattentiveness, aggression, and anxiety (Meyer & Batshaw, 2002).

About 70% of carrier females show no clear physical, cognitive, or behavioral problems. The rest show a variety of symptoms, less severe than in males, including mild MR, learning disabilities, communication problems, and emotional disturbances. Frequent learning disabilities include problems in visual-spatial skills, executive function, and simultaneous processing. Language problems, similar to those of males, include cluttered and perseverative speech.

Relationship to Autism

Many of fra(X)'s characteristics are similar to those of autism and other pervasive developmental disorders. About 7% of children with autism have fra(X), and 15–28% of those with fra(X) meet criteria for autism (Meyer & Batshaw, 2002). Thus, boys diagnosed with autism are now routinely screened for fra(X). However, the disorders appear to be separate. For example, severe autism rarely occurs with fra(X) (Bailey et al., 1998), and a study (Klauck et al., 1997) of a large sample of autistic boys found no true association between fra(X) and autism.

Treatment

A team approach is recommended (e.g., Hagerman & Lampe, 1999). Stimulant medications, clonidine, and folic acid are commonly used to reduce Attention-Deficit/Hyperactivity Disorder symptoms and temper tantrums, but owing to differential response, no one drug regimen is effective. Antiseizure medications may help control not only seizures but also mood swings and aggression. Selective serotonin reuptake inhibitors are often effective for mood swings, anxiety, and aggression. Speech/language, physical, and occupational therapy are almost always helpful. Fra(X) children respond well to highly structured multimodal learning environments, including computer-assisted instruction that provides immediate feedback. Behavioral therapy is particularly effective in managing problem behaviors. Given the variable characteristics of fra(X) children, detailed psychological assessment is important for the design of appropriate individualized instruction.

FREE WILL

In psychology and in psychologically oriented philosophy two extreme positions have been taken on the question of free will. One—widely associated at present with psychology and often presented as a basic assumption in introductory textbooks of general psychology—is that free will is entirely illusory and that in order to be scientific psychologists must believe that all human behavior or experience is absolutely determined by causal processes that are in principle knowable. The other extreme, especially associated in this century with the existentialist movement in philosophy, is that human free will is real and ubiquitous in the sense that all experience and action involve some element of free choice, that with no change in the antecedent conditions one could always have experienced or acted somewhat differently from the way one did.

Among psychologists, the extreme deterministic position often seems to be based on the belief that it is taken by, and is somehow essential to, the physical sciences, and that it must be a basic assumption of any genuinely scientific enterprise. Quantum physics has accepted some degree of indeterminacy as an inevitable principle. Conditions, the knowledge of which would be needed for perfect predictability in psychology, would often include internal processes that could not be accurately known without interventions that would change them and hence the outcome; this seems sufficiently analogous to the basis for indeterminacy in quantum physics to argue for extension of the principle to psychology. Once indeterminacy is granted to be inevitable, a distinction between free will and a determinism that cannot possibly be verified may become scientifically meaningless.

The argument for free will is most often empirical. Having acted, a person often feels certain that he or she could have acted differently, could have made a different choice; free will, it is argued, is thus a basic fact of experience. This argument cannot escape the objection that causal determinants may simply not yet be sufficiently identified and understood.

Another pragmatic basis for a choice of positions on the issue of free will is the effect of various positions on general human welfare. Advocates of rigid determinism sometimes consider acceptance of their position necessary for convincing people that human behavior can be predicted and controlled, so that the future of humanity can be influenced by "human engineering" just as physical events can be influenced by engineering based on the physical sciences. Opponents of rigid determinism argue that acceptance of that position eliminates hope of deliberate change and thus has a detrimental influence.

FRIENDSHIP

Friendships are important relationships in all cultures and throughout the lifespan. Friendships are characterized by several defining features: (1) they are dyadic relationships; (2) there is an affective bond that is reciprocated; (3) they are voluntary; (4) they are typically egalitarian in nature; and (5) almost all entail some shared activities and companionship. Friendships often meet other functions as well, such as serving as a source of support and providing opportunities for self-disclosure and intimacy.

These features differentiate friendships from several related phenomena. The fact that they are dyadic relationships distinguishes them from cliques or groups of peers. (Of course, many members of cliques are also friends with other members.) Similarly, having friendships is different from being popular. Individuals who are not popular may have close friendships, and, less commonly, a popular person may not have a close friendship. The reciprocal nature of friendship differentiates actual friendships from relationships in which one person thinks or wishes it were a friendship. The strong affective bond distinguishes friendships from acquaintanceships. Friends provide individuals with more support than acquaintances, although friends do not necessarily engage in less conflict than acquaintances. Finally, romantic relationships are considered a special form of friendship, and in fact romantic partners are commonly seen as one's best friend.

Friendship Selection

Who becomes friends? Two key predictors of friendship formation are proximity and similarity. Friends usually live near each other, attend the same school, or work near each other. Proximity makes it more likely that individuals will have the opportunities to interact with each other and to develop a friendship. In addition, contrary to the adage "opposites attract," friends are usually similar to one another. They tend to be of the same age, gender, and socioeconomic and ethnic background. Moreover, friends commonly share interests and tend to develop more similar interests and values over the course of being friends. Individuals who are dissimilar are less likely to remain friends.

Friendships Across the Lifespan

Individuals of almost all ages develop friendships. Approximately 75% of preschoolers report having friends, and the percentage increases to over 90% by adulthood; the proportion remains high through adulthood, although about 15% of the elderly report not having friends. It is debatable whether very young children have true friendships, although even toddlers prefer some playmates to others. Preschoolers' friendships are typically based on shared activities and tend to be less long-lasting than friendships

later in life. One of the most striking developmental changes in friendships occurs in preadolescence, when children begin to develop *chumships.* These relationships are usually with a same-sex peer and involve more intimacy, self-disclosure, support, and acceptance than earlier friendships. Chumships are thought to be a precursor for adult friendships and romantic relationships. In adolescence, other-sex friendships become more commonplace, and romantic relationships begin to emerge. In addition, adolescents and adults often develop specialized friendships wherein one turns to different friends for different purposes. Throughout adulthood, friendships remain important, although they may not be as central as a romantic relationship.

Friendship and Gender

Friendships develop more often between members of the same gender than between males and females. Other-sex friendships are particularly infrequent during the elementary school years, accounting for less than 20% of friendships during this time. These friendships occur less commonly because of structural barriers and cultural norms. Differences also exist in the typical nature of friendships of males and females. For instance, female friendships tend to be characterized by more intimacy and self-disclosure than male friendships, and this distinction becomes particularly notable in adolescence. Closeness in male friendships may occur through shared activities; sometimes experiencing a very stressful event together can also foster closeness. During childhood and adolescence, girls tend to be more exclusive in their friendships than boys are.

Significance of Friendships

Friendships play an important role in development and adjustment in several ways. One reason is that they are egalitarian in nature. Whereas parents ultimately have more power in parent-child relationships, friends are on equal footing. Accordingly, what friends do together or how they behave toward each other is more open to negotiation. As a result, children obtain valuable experience in learning how to express their own wishes and compromise with another person in a way that they can't learn by interacting with a parent or other authority figure. In addition, friendships provide a ready venue for communicating information about peer norms and values, as well as about taboo topics such as sex.

These contrasts between friendships and parent-child relationships do not mean that friends and parents are opposing social influences. Contrary to some depictions in the popular media, friends and parents more commonly have similar influences on children and adolescents. Typically children select friends whose values are congruent with their parents' values. Moreover, both parents and friends are likely to affect individuals' behavior. For example, whether both an adolescent's friends and parents smoke influences the likelihood of his or her choosing to smoke. The strongest clashes between the influences of friends versus parents occur when relationships with parents are strained.

Empirical research has repeatedly found links between healthy adjustment and having friendships. Well-adjusted individuals are more likely to develop friendships, and friendships seem to promote adjustment. It seems particularly important that one have at least one close friendship. Although friendships are generally thought to have a positive influence on adjustment, the specific effects vary as a function of who the friend is. Thus, having a friend who is deviant or antisocial is likely to foster deviant or antisocial behavior. Similarly, conflictual, problematic friendships can have deleterious effects.

Both having friendships and being accepted (versus rejected) by one's peers contribute to well-being. Similarly, the characteristics of relationships with both parents and friends contribute to adjustment and development. In effect, friendships share features with other close relationships but also have their own unique features and make their own contribution to individuals' lives.

FROMM'S THEORY

Eric Fromm was concerned about a diversity of topics related to his search for the essence of human nature. He combined several humanist approaches to define human nature as essentially dynamic and dialectic. According to Fromm, the essential in man is his capacity to act with freedom and to understand love as an objective communion. He considered people essentially equal, without sexual or status differences.

Self-awareness, reason, and imagination disrupt the harmony that characterizes animal existence. The emergence of these traits made humankind into an anomaly, a freak of the universe. Part of nature, subject to physical laws and unable to change them, humans transcend the rest of nature. Being aware of ourselves, we realize our powerlessness and the limitations of our existence. We visualize our own end—death.

Fromm referred to needs rooted in the peculiarity of human existence. These include the need for relationship, because feeling isolated leads to disintegration just as inanition leads to death. Also, there is the need to transcend, to rise above the possivity and accidentality of our existence; this need makes us become original and look for freedom.

The need to transcend offers us the option to create or to destroy, to love or to hate. The satisfaction of the need to create induces us to happiness, destruction, or suffering. A third need is rootedness, which leads us to security and helps us to avoid anxiety and loneliness. A fourth need, identification, gives us a concept of self, since we need to feel and say, "I am myself." A fifth need, orientation, is a peculiar need based on our existential situation, humanity, imagination, and reason; it refers to the purpose of finding a sense for or a value to existence.

For Fromm, social character implied the adaptation of free individuals to social conditions that develop the character traits inducing them to behave in the same way that, within their culture, most people do. Social character internalizes the external needs, orienting individuals toward tasks required by the socioeconomic system.

FUNCTIONAL ANALYSIS

Definition

Functional analysis is a strategy for the assessment and treatment of mental health problems with origins in behaviorism. It is generally viewed as a subfield within the larger realm of behavioral assessment and behavior therapy. More specifically, functional analysis is a set of procedures that attempts to identify important contextual variables such as history and environment that help to cause and/or maintain problematic behaviors or behavior-environment interactions. The goal of functional analysis is to effectively identify targets of intervention that are alterable such that appropriate treatments may be rapidly implemented and evaluated through concentrated intervention efforts.

History

When a client seeks psychological or psychiatric intervention for a mental health or behavioral problem, the obvious questions are "what created and maintains the problem?" and "how can the problem be solved?" Assessment procedures are the data-gathering tools that are used to investigate the former question and to inform the latter one. Assessment is sifting through the multitude of facts that comprise a person's life and determining which historical and current aspects are relevant to the development and/or maintenance of the problem. Traditionally this process resulted in classifying problems and, by extension, individuals with those problems into diagnostic categories based on commonalities in apparently relevant variables. These categories are designed to describe syndromes and to guide clinical interventions.

Behaviorists have questioned the usefulness of diagnosis and syndromal classification systems such as the *Diagnostic and Statistical Manual* of the American Psychiatric Association on many grounds. Of particular relevance to functional analysis are the significant varieties in symptom presentation that comprise a single category. It is argued that symptom overlap does not equate with a unique, full-fledged kind of mental disorder. As a result, newer approaches to assessment that consider the function of behaviors over the topographical form of the behaviors, and that attend more closely to individual differences in behavior, have been explored. The product of this desire to understand behavior functionally and idiographically is functional analysis.

Functional analysis is a term that has been used interchangeably with several others in the behavioral literature, including *behavioral analysis, behavioral assessment, functional behavioral analysis,* and *behavioral case formulation.* Compounding the confusion is that just as many terms are used to refer to the same procedures, *functional analysis,* is used to refer to a diversity of procedures in the literature. This phrase has been used to describe any part of the process that includes discovering the variables of which behavior is a function, designing an intervention for the environment or behaviors, implementing the intervention, reevaluating the case conceptualization based on response to treatment, and recycling the process until the problem subsides. Although some behavior analysts focus exclusively on the assessment portion of this intervention process, others consider the whole process to be a complete functional analysis.

Procedures

Functional analysis derived from basic behavioral principles. It attends to the antecedents, stimuli, responses, consequences, and contingencies that produce and/or maintain effective or ineffective behaviors. The identification of pertinent, controllable variables in this sequence and the effective treatment of those variables to produce different outcomes are its challenges. The basic form of a functional analysis is as follows.

1. Identify aspects of the client and his or her environment or history that may be relevant to the problem.
2. Organize information about potentially relevant variables according to behavioral principles in order to identify possible causal relationships among variables.
3. Collect additional detailed information about potential causal variables in order to complete the analysis.
4. Identify or create a treatment hypothesized to produce a desired increase or decrease in the frequency

or intensity of the causal variables based on the case conceptualization of how the variable functions for the individual.

5. Implement the intervention for one variable at a time and observe any change in the problem.
6. If there is no change in the target behavior, remove the original intervention, move to the next suspected causal variable, and implement and evaluate the treatment of that variable.
7. If the problem is not alleviated, return to the case conceptualization to identify alternative variables that may be pertinent or alternative causal relationships and continue with the steps of the functional analysis.
8. Continue to revise the conceptualizations and interventions until the problem is solved.

Strengths and Weaknesses

Strengths

The strengths of functional analysis are the precision with which cases may be conceptualized and the direct link to treatment implementation. Instead of relying on imprecise diagnostic categories as heuristics to guide conceptualizations of the problem, both case conceptualizations and treatment planning focus on the unique aspects of the particular problem. These unique aspects of the problem are the points of customized clinical interventions instead of a generic syndrome-level intervention.

Weaknesses

The weaknesses of functional analysis stem from its lack of specificity. Communication between mental health professionals and replication of assessment, treatment, and treatment evaluations are impeded by the imprecision of functional analysis language and procedures. When different terms are being used for functional analyses, relevant information may not be shared because it is not identified as belonging to the functional analysis category. Similarly, when *functional analysis* is used to refer to overlapping or altogether different procedures, miscommunications may occur because the discussants are working from different assumptions about the procedures that are involved. Moreover, as communication is increasingly removed from direct observations of client behaviors, there are greater opportunities for miscommunications to arise. If clinicians that are familiar with functional analysis have difficulties communicating effectively with one another, how much more difficult it is to create and maintain clear lines of communication with administrators and insurance representatives. Functional analysis is therefore difficult to administer and justify from a systemic perspective.

A related problem is replication. *Functional analysis* currently refers to a range of assessment and intervention procedures. Without a standard of practice for the subfield, clinicians may perform different sets of procedures and call each of them a functional analysis. As a result, there is no guarantee that one clinician's conclusions are going to match another professional's conclusions in the same case. This lack of replicability distills confidence from the assessment procedures, which dilutes their effectiveness. Furthermore, if a functional analysis cannot be replicated, doubt is cast on the ability to reliably study the phenomenon. This replicability problem ironically renders an assessment and intervention procedure that arose out of the behavioral empirical literature untestable.

Future Directions

The field of behavior analysis acknowledges the strengths and weaknesses of functional analysis and is beginning to propose improvements. Suggestions have been made that promote standardizing the definition of functional analysis and the procedures that comprise such an analysis in order to advance communication and replication. Additional proposals have been made to strengthen the communication aspect of the procedure. The development of a nomothetic classification system that is based on functional analysis has been offered. Proposed variations of this taxonomy include expert systems, logical functional analytic systems, or functional diagnostic systems, each based on functional analyses.

In addition to more advanced clinical applications, researchers have segued into an expanded use of functional analysis as a research strategy. Compiling and analyzing functional analytic data within and across clients may contribute to the basic understanding of many behaviors and behavior-environment interactions.

FUNCTIONAL AUTONOMY

Gordon W. Allport coined the term *functional autonomy* to refer to motives that have become independent of the needs on which they were originally based.

When first introduced, this concept of functional autonomy was both radical and controversial. The motivational theories prevailing in North American psychology focused almost exclusively on mechanisms directly linked to basic physiological needs. In contrast, Allport's functional autonomy raised the possibility that motives could function quite independently of any physiological need or drive. This liberalized conceptualization of motivation had important implications for several key issues in psychology. It provided an image of the individual as an active agent rather than a passive entity entirely under the control of biological needs and immediate stimuli. It allowed for explanations of behavior that emphasized the present and the future rather than the past. It also pointed to the role of complex and unique patterns of motives in shaping and defining individual personality.

In contemporary psychology, the idea of functionally autonomous motives has been accepted into the mainstream of psychology.

FUNDAMENTAL ATTRIBUTION ERROR

Attribution theory is concerned with the causes that people assign to behaviors in their attempts to explain them. The inferences about causation of a person's actions fall into two broad categories: internal (characteristics of the person) and external (characteristics of the social or physical environment). The fundamental attribution error (FAE), sometimes called *actor-observer asymmetry* or *overattribution,* is the general tendency of an observer to perceive another person's behavior to be caused by internal, personal characteristics or dispositions, rather than external, situational influences. Conversely, the behaving person (the actor) tends to see his or her own behavior as caused by the situation. The concept of FAE grew out of an extensive body of research on social perception and cognition, and in turn the idea has stimulated much research. There may even be attributional thinking in primates. In human beings, this well-established observer overemphasis on personal traits and underemphasis on context raises serious questions about bias in many situations in which people judge other people, such as jury decisions, voting for political candidates, and clinical assessment and treatment.

This prominent tendency to overattribute internal causes had been recognized by early social psychologists, such as Fritz Heider in 1958, as an actor-observer effect, and in further research Lee Ross in 1977 gave FAE its name. Typical experiments might involve judging statements allegedly made by persons under various conditions, or comparing subjects' explanations for their own choices and the choices made by others. Subjects might report causes of actions while viewing themselves or another person on videotapes. The FAE process is so strong that even when the observer is told something about the situational conditions of the actors, there is a tendency to attribute others' actions to personal traits. In daily life, this seems related to "blaming the victims" of rape, poverty, and other social problems. In organizations, people may overattribute responsibility to individuals, such as leaders, when there are structural or system faults. Since psychology in general focuses on individual variables, there is a strong likelihood that psychologists will overattribute observed results to individual dispositions. Some measures of individual differences are available, for instance, the Attributional Style Questionnaire and the Causal Dimension Scale.

There are several approaches to explaining FAE. A common explanation involves differences in the amount and type of information available to actors and observers. Persons looking at their own behavior have much previous behavior against which to compare it. When people make attributions to others, they seldom have the same amount or kind of information available. Also, actors and observers differ in information that is salient or striking to them—what is figure and what is ground.

The application of attribution theory to clinical work is of considerable importance. Some studies have shown that a dispositional or individualistic bias may exist among professional helpers, but this bias has not been clearly proven. Since, however, the tendency to overattribute problems to personal characteristics is common in the general population, it would seem important in clinical training to help students examine their explanations of clients' feelings and behaviors. Conversely, counselors and clinicians may use FAE as part of "attribution therapy," helping the client to reframe self-attributions. Depressed patients tend to use self-blame much more than others. Some studies have shown that cognitive therapeutic instruction to decrease overattribution of negative events helps to reduce depression or immunize people against a sense of helplessness.

Other interesting areas of application of the FAE principle are in legal and international situations. Questions such as the following arise: What was the intent of an individual alleged to have committed a crime? What does he or she see as reasons or causes for doing the deed? How about witnesses and attribution errors? In regard to the security problems of nations, FAE exacerbates attribution of hostile intentions to others and leads even peaceful states to arm excessively. Policy makers see arming themselves as a defensive action and assume that others' military buildups are aggressive. Social identity theory suggests that ob-

servers will tend to perceive in-group members as similar to themselves and therefore give situational explanations for discrepant behavior but will attribute out-group responsibilities differently.

There are several cautions and limitations about the FAE bias. It is important to note that FAE refers to a relative tendency of observers to attribute to the actor more responsibility for behavior than does the actor; it does not say anything about accuracy of causal claims. There are few research attempts to determine the reality or truth of attributions; questions may be raised about the accuracies of the observer, the actor, or both. Another caution is that oftentimes observers make personal attributions because of efficiency; if information about the actor's situation is not available, it may not be possible or practical to take the complexity of the actor's view into account. Attitudes in the attributional process are also important; the actor-observer differences may be diminished by an observer's empathic attitude or personal acquaintance with the actors and their situations. There seem to be cultural differences in the FAE tendency; North Americans and Westerners in general may have a bias toward blaming the individual in contrast with people in India and China or other collectivist or more holistic cultures. Easterners may tend to take situational information more into account when that is available. Sabini claims that FAE is pancultural in that it involves saving face and embarrassment.

Considerable work needs to be done to clear up the theoretical confusions about how FAE relates to similar concepts such as general social identity, theories of mind, self-efficacy, and internal and external locus of control. There is a difference between giving "mere causes" for behaviors as compared with reasons that involve intentions and show the logic that was used in the process.

G

GABA RECEPTORS

It is now universally recognized that γ-aminobutyric acid (GABA) synthesized by the two molecular forms of glutamic acid decarboxylase (GAD65 or 67) expressed in neurons functions as a key neurotransmitter from crustaceans to mammals.

$GABA_A$ Receptors

In the brains of vertebrates, GABA mediates synaptic inhibitory events by binding to specific recognition sites located in various members of a pentameric protein family, including a transmembrane anion channel, which is termed $GABA_A$. When two molecules of GABA bind to a $GABA_A$ receptor molecule, the opening frequency of the anionic channels increases and, most of the time, Cl^- ions flow inwardly. In 1952, Hodgkin and Huxley suggested that in voltage-operated Na^+ and K^+ channels, the gating and its ion permeation are two independent processes. The idea that the gating opens and closes the channels but pays scant attention to the behavior of fully activated channels might also apply to the $GABA_A$-gated receptor channels. The binding of the two GABA molecules to a $GABA_A$ receptor molecule activates that Cl^- channel; in contrast, the binding to positive or negative allosteric modulatory sites of hormones (neurosteroids) or endogenous modulatory ligands (endozepines) affects the ohmic behavior of the channel by changing either the open time duration or the opening frequency of the Cl^- channels gated by GABA. Some of these modulatory sites also function as the high-affinity binding sites for important drugs used during surgery to induce anesthesia (barbiturates) or in psychiatry for the treatment of Anxiety or Mood Disorders (benzodiazepines [BZ]). Both drugs amplify the GABA-gated Cl^- current intensity and thereby decrease retention of recent memories, reduce learning speed, and induce sedation. Anesthesia is induced by barbiturates and not by BZs because only barbiturates can gate the $GABA_A$ receptor channels in the absence of GABA.

$GABA_B$ Receptors

The family of metabotropic GABA receptors was identified after the ionotropic $GABA_A$ receptor family. The activation of $GABA_B$ receptors by GABA decreases the rate of cAMP formation and this metabotropic function differentiates these receptors from ionotropic $GABA_A$ receptors. The $GABA_B$ receptors were further characterized by their insensitivity to bicuculline inhibition and muscimol stimulation (typical of $GABA_A$ receptors) by a specific inhibition by a number of selective antagonists inactive on $GABA_A$ receptors and by their selective stimulation by baclofen, which does not stimulate $GABA_A$ receptors. Confirmation of the metabotropic nature and of their functional association to G proteins has been accomplished by cloning two specific DNA sequences (each encoding for a slightly different 7-transmembrane domain protein) which, functioning as dimers, inhibit adenylate cyclase or gate K^+ channels using various G protein subtypes as second messengers.

The complete structural and functional distinction between $GABA_A$ (ionotropic) and $GABA_B$ (metabotropic) receptors has a clear parallel to that between nicotinic (ionotropic) and muscarinic (metabotropic) acetylcholine receptors and ionotropic and metabotropic receptors for the transmitter glutamate.

$GABA_C$ Receptors

This third family of ionotropic receptors ligated by GABA is insensitive to bicuculline inhibition, baclofen or muscimol stimulation, and positive allosteric modulation by BZs.

The ionotropic responses elicited by GABA acting on $GABA_C$ receptors are also of the fast type associated with an opening of an anion channel. The $GABA_C$ receptor structure results from homomeric assembly of ρ (ρ_1, ρ_2, ρ_3) subunits. The only organ that expresses ρ subunits in both rat and human is the retina. Since these ρ subunits have a 27% homology to $GABA_A$ receptor subunits, they have been considered a subgroup of these receptor subunits. However, unlike $GABA_A$ receptors, when ρ subunits combine to form $GABA_C$ receptors, they form only homomeric receptors. Thus, the function of homomeric ρ receptors sharply differs from that of $GABA_A$ receptors because ρ subunits lack the regulatory sites that are expressed in α, β, and γ subunits. The resistance of $GABA_C$ receptors to bicuculline inhibition or muscimol stimulation and the absence of allosteric modulation sites for barbiturates and BZs justify maintaining a functional distinction between $GABA_C$ and $GABA_A$ receptors.

Characterization of $GABA_A$ Receptor Functional Modifications by Various Anxiolytic Drugs Acting on the BZ Recognition Site

There is considerable interest in the availability of an effective $GABA_A$ receptor-acting anxiolytic drug that will not share the problems of presently available medications. These problems are tolerance, dependence liability, and several inconvenient side effects such as sedation, induction of recent memory deficit, barbiturate or ethanol potentiation, and ataxia. The high-affinity binding site for BZs located in $GABA_A$ receptors has specific structural features. One consists of a binding pocket formed by the contiguity of an α subunit (not present in α_6 and with low intrinsic activity in α_5) with a γ_2 or γ_3 subunit (which is not expressed by a γ_1 subunit). These requirements should predict which $GABA_A$ receptors are susceptible to positive allosteric modulation by ligands to the BZ recognition sites, that is subunit isomerism and sequence. Unfortunately, we do not have suitable methods to fulfill either task. It is presently believed that BZs amplify the actions of GABA by facilitating the opening of channels in monoligated $GABA_A$ receptors that, in order to open the channels in the absence of BZs, require two molecules of GABA bound to the receptor.

GAMBLING, PROBLEM

Gambling in the United States

The past 2 decades have witnessed significant increases in legalized gambling opportunities in the United States. These opportunities have been accompanied by record levels of gambling expenditures. Over 10% of every dollar that Americans spend on leisure is spent on gambling.

Increase in gambling availability has also been accompanied by an increase in problem gambling behavior. Over 5% of adults have experienced significant problems related to gambling, and 1% of adults meet criteria for Pathological Gambling Disorder. Higher rates of problem gambling have been reported among males, youth, college students, African Americans, and individuals with easy access to gambling.

Problems Associated with Excessive Gambling

The most basic consequence of excessive gambling is financial. To deal with their debts, problem gamblers often must turn to other sources for money, including family; friends; or criminal activities, such as embezzlement. As a result of insufficient financial resources many gamblers file for bankruptcy. Arrest and incarceration due to illegal activities aimed at securing more money are also common.

Problem gamblers are more likely to suffer from depression or alcohol problems. They report greater rates of psychological distress and more use of psychiatric treatment. Problem gamblers often experience serious relationship difficulties. Spouses and family members must cope with the consequences of the gambler's behavior, including absence from the home, distrust of the gambler, and stress over family finances. Among problem gamblers, divorce rates are higher than the national average.

Pathological Gambling Disorder

Pathological Gambling Disorder was officially recognized as an impulse control disorder by the American Psychiatric Association in 1980 (*Diagnostic and Statistical Manual of Mental Disorders,* third edition [*DSM-III*]). *DSM-III* criteria include (1) preoccupation with gambling, (2) wagering larger amounts of money to experience excitement, (3) feelings of withdrawal when trying to control gambling, (4) gambling to escape problems, (5) chasing losses, (6) lying to others to conceal gambling involvement, (7) committing illegal acts to obtain money to gamble, (8) jeopardizing important relationships or opportunities because of gambling, (9) relying on financial assistance from others to pay gambling debts, and (10) unsuccessful efforts to limit gambling. These criteria were fashioned after the criteria for Substance Use Disorders and are based on the assumption that gambling may be similar to addictive behaviors.

Models of Problem Gambling: Medical

A variety of explanatory models for problem gambling have been developed. The disease model views problem gambling as a medical illness. Excessive gambling behavior is considered a chronic condition that manifests itself in clear signs and symptoms. Many explanations for the cause of the disease have been offered. Psychodynamic theorists have explained that gambling may fulfill an individual's instinctual drives; however, the nature of the psychodynamic position has not allowed researchers to support or refute it.

Genetic research has suggested that problem gamblers may inherit a genetic predisposition to gamble excessively. However, genetic factors appear to be only one important component in the development of gambling problems.

Models of Problem Gambling: Psychological

Psychologists have attempted to understand the role of psychological factors in the development of gambling problems. Theorists who have examined the relationship between gambling and personality traits, such as sensation-seeking, extroversion, and locus of control have generated only limited support for the role of personality in gambling.

Behavioral theorists have used learning models to explain how individuals develop gambling-related problems. According to operant conditioning theory, individuals gamble because they have been reinforced on a variable ratio schedule. Occasional wins serve to maintain the gambling behavior. Behavioral theories have difficulty with the seemingly irrational basis of gambling behavior.

In recent years, models of problem gambling have increasingly focused on the role of cognition. These cognitive models are based on empirical evidence that irrational beliefs are related to gambling behavior. According to cognitive theory, many gamblers hold beliefs that lead them to continue to gamble, despite the odds and their mounting losses. Belief in luck and the ability to control chance events are examples of irrational beliefs that may lead to problematic gambling behavior.

At the core of problem gambling behavior is a lack of self-regulation. Problem gamblers fail to control their gambling behavior and experience the resulting consequences. Although early treatment models were based on medical models of problem gambling, more recent treatment strategies have shifted to cognitive and behavioral perspectives.

Treatment of Problem Gambling

For the small number of problem gamblers who seek treatment, the most available option is Gamblers Anonymous (GA). GA is a self-help group based on the disease model of problem gambling and is focused on a 12-step program emphasizing group support, faith, and commitment. GA members share with the group their story about how excessive gambling led to problems. Complete abstinence from gambling is considered the only viable treatment goal. Members are encouraged to be actively involved in the program even after extensive periods of abstinence to avoid relapse. Research has suggested that GA is beneficial for a small percentage of those who attend.

A variety of behavior therapy strategies have been administered to problem gamblers including aversion therapy, in vivo desensitization, imaginal desensitization, and cue exposure and response prevention. Although most of these programs lack stringent evaluation, outcome data have generally supported their efficacy.

More recent therapy developments have focused on a cognitive model of problem gambling. These treatments use cognitive restructuring techniques designed to change gamblers' irrational beliefs about gambling. Cognitive strategies are often combined with problem-solving skills training and training to identify and cope with situations that present a high risk of relapse.

It is likely that future treatment strategies for problem gambling will build on contemporary models that have been developed in the alcohol treatment field or models that are specific to problem gambling. For example, brief, motivationally based treatment programs, which have received empirical support as effective alternatives to traditional abstinence-based interventions for alcohol problems, are now being adapted and tested to help problem gamblers.

The growing availability of gambling, the recognition of individual and societal problems associated with excessive gambling, and the increasing attention of scientists and clinicians suggest that the area of problem gambling will be a dynamic one.

GATE CONTROL THEORY OF PAIN

The theory of pain that we inherited in the twentieth century was proposed by Descartes three centuries earlier. Descartes's specificity theory of pain proposed that injury activates specific pain fibers that, in turn, project pain signals through a spinal pain pathway to a pain center in the brain. The psychological experience of pain, therefore, was virtually equated with peripheral injury. In the 1950s, there was no room for psychological contributions to pain, such as attention, past experience, and the meaning of the situation. Instead, pain experience was held to be proportional to peripheral injury or pathology. Patients who suffered chronic pain syndromes without presenting signs of organic disease were labeled as crocks and sent to psychiatrists. The picture, in short, was simple. However, to thoughtful clinical observers, it was clearly wrong (Livingston, 1943; Noordenbos, 1959).

In 1965, Melzack and Wall proposed the gate control theory of pain, based on the following propositions:

1. The transmission of nerve impulses from afferent fibers to spinal cord transmission cells is modulated by a spinal gating mechanism in the dorsal horn.
2. The spinal gating mechanism is influenced by the relative amount of activity in large-diameter and small-diameter fibers: Activity in large fibers tends to inhibit transmission (close the gate), whereas small-fiber activity tends to facilitate transmission (open the gate).

3. A specialized system of large-diameter, rapidly conducting fibers (the central control trigger) activates selective cognitive processes that then influence, by way of descending fibers, the modulating properties of the spinal gating mechanism.
4. When the output of the spinal cord transmission cells exceeds a critical level, it activates the action system—those neural areas that underlie the complex, sequential patterns of behavior and experience characteristic of pain.

When the gate control theory was published, it generated vigorous (sometimes vicious) debate as well as a great deal of research to disprove or support the theory. It was not until the mid-1970s that the gate control theory was presented in almost every major textbook in the biological and medical sciences. At the same time there was an explosion in research on the physiology and pharmacology of the dorsal horns and the descending control systems.

The theory's emphasis on the modulation of inputs in the spinal dorsal horns and the dynamic role of the brain in pain processes had both a clinical and a scientific impact. Psychological factors, which were previously dismissed as reactions to pain, were now seen to be an integral part of pain processing, and new avenues for pain control were opened. Similarly, cutting nerves and spinal pathways was gradually replaced by a host of methods to modulate the input. Physical therapists and other health care professionals, who use a multitude of modulation techniques, were brought into the picture. The current status of pain research and therapy has recently been evaluated (Melzack & Wall, 1996) and indicates that, despite the addition of a massive amount of detail, the theory has remained basically intact up to the present time.

The gate control theory's most important contribution to pain research and therapy is its emphasis on the central, rather than peripheral, nervous system (Melzack & Wall, 1996; Melzack, 1998, 1999). The great challenge at present is to understand brain mechanisms. Melzack and Casey (1968) made a start by proposing that specialized systems are involved in the sensory-discriminative, motivational-affective, and evaluative dimensions of pain. The McGill Pain Questionnaire, which taps into subjective experience, is widely used to measure pain (Melzack & Torgerson, 1971; Melzack, 1975). We have also begun to understand the different pathways and neural mechanisms that underlie acute and chronic pain—again, by invoking complex spinal and brain mechanisms—and we have gained a far better understanding of analgesic drugs (Wall & Melzack, 1999).

In 1978, Melzack and Loeser described severe pains in the phantom body of paraplegics with verified total sections of the spinal cord, and proposed a central "pattern generating mechanism" above the level of the section. They focused more powerfully than ever before on central nervous system (CNS) mechanisms. Recent studies have explored new theoretical concepts to explain phantom body experiences—from pain to orgasm—in people with total spinal sections (Melzack, 1989). These experiences reveal important features of brain function because the brain is completely disconnected from the cord. Psychophysical specificity, in such a concept, makes no sense, and we must explore how patterns of nerve impulses generated in the brain can give rise to somesthetic experience.

GENDER ROLES

Gender roles are the set of expectations a society has about males and females. These expectations are multifaceted and include specifications about appearance, personality traits, emotions, interests, abilities, and occupations. For example, in Western societies men are generally expected to be more agentic and less emotional than women, and women are expected to be more communal and less aggressive than men. Furthermore, men are often assumed to

have paid occupations and to be financially responsible for their families, whereas women are assumed to be homemakers with primary responsibility for the children. Such beliefs serve to define what behaviors are considered appropriate or inappropriate for each gender. Thus, gender roles do more than merely describe the way things are; they describe how things should be.

Gender roles serve both social and intrapsychic functions. With respect to the former function, gender role expectations guide people's judgments and evaluations of others. When one assumes that another person possesses certain characteristics on the basis of his or her gender, one is engaging in *gender stereotyping*. Gender stereotyping is pervasive and can influence judgments in a subtle, nonconscious, and unintended manner. Gender roles also influence interpersonal evaluation directly: A person who conforms to the appropriate gender role is likely to be evaluated positively, whereas deviation from that role may result in avoidance, disapproval, or even outright hostility. Gender roles serve an intrapsychic function by helping people to define themselves as individuals and to guide their behavior. Importantly, however, people do vary in the extent to which they identify with a given gender role. That is, not all men view themselves in traditionally masculine terms, nor do all women identify with a traditionally feminine image. The extent to which one shares the constellation of characteristics associated with a particular gender role is known as *gender role identity.*

The measurement of gender role identity typically focuses upon personality traits (e.g., agentic versus communal), with individuals indicating on a paper-and-pencil survey the degree to which each trait provides a true description of themselves. Note, however, that measurement of gender role identity is not without some debate. Traditionally, masculinity and femininity are considered to be opposite ends of a single continuum (i.e., if you are high in femininity, you must be low in masculinity). More modern theorists, however, view masculinity and femininity as independent characteristics (i.e., you can be high or low on both dimensions, as well as high on one and low on the other). Persons describing themselves as being both strongly masculine and strongly feminine are labeled *androgynous.* Alternately, gender role identification may be conceptualized as a stagelike process wherein androgynous individuals are those who have transcended or rejected traditional gender roles. In this case, androgyny is viewed as the last stage of gender role identification.

There are a number of theories regarding how individuals become gender identified (also known as *gender typed*). One of the earliest formal theories, proposed by Freud, suggested that individuals must pass through a series of stages (oral, anal, phallic, genital, and latency) in order to become appropriately gender typed. According to this view, successful gender typing was argued to occur when children learn to identify with their same-sex parent and, in doing so, adopt the qualities and characteristics of that parent. Despite the popular attention paid to this theory, there is little empirical evidence to support it. More modern theories generally fall within the nature or nurture traditions. The theory that best represents the biological or nature tradition focuses upon the role of evolution in shaping each gender's interests, traits, and behaviors. In particular, this theory suggests that contemporary differences in male and female gender roles are, in effect, carryovers from those interests, traits, and behaviors that were adaptive for our ancestors. For example, the observed gender difference in the number of sexual partners desired is thought to have originated from gender differences in the sexual strategies found to be successful in the ancestral environment.

On the other hand, the socialization or nurture account argues that parents and other adults influence behavior by rewarding appropriate gender role behavior and punishing inappropriate role behavior. For example, parents may praise obedience and punish aggressiveness in their daughters and praise risk taking and punish crying in their sons. This theoretical account has more recently included *cognition* as an important intervening variable. Rather than suggesting that children are merely shaped by external forces, social cognitive learning theory argues that the process of receiving reinforcements and punishments for gender-appropriate and gender-inappropriate behavior results in the creation of cognitive expectancies that come to guide future behavior. Furthermore, this account suggests that receiving rewards and punishments is not the only means by which children learn gender-appropriate behavior. Significant adults may also impact gender typing by modeling behavior. Children learn to imitate those behaviors they see adults of their same sex performing. Although theories tend to follow one or the other tradition (nature versus nurture), these two general accounts need not be antagonistic or independent. Today, most psychologists who study gender typing recognize that biology and socialization likely work together to shape gendered behavior; it is no longer necessary to decide between nature *or* nurture, but to acknowledge the influence of nature *and* nurture.

Regardless of origin, it is important to convey that gender roles are neither static nor invariant. For example, male and female gender roles are far more discrepant from one another in some cultures than in others, with men and women sharing little in the way of daily activities. Furthermore, what may be considered masculine in one culture may be perceived as feminine in another. For example, while Western cultures expect women to be more emotionally expressive than men, Middle Eastern cultures expect the reverse. Gender roles also vary over time. Within the United States alone, gender roles have changed tremendously in the last 50 years, with far fewer people expecting, for example, married women to confine their activities to the home. Gender roles also change as we age. Research indicates that both women and men adhere less to gender roles as they mature beyond middle age, an occurrence that

could be explained by either nature (hormones) or nurture (differential role demands).

Scientists have long debated the degree to which males and females differ in their traits, interests, and behavior. Consensus is emerging, however, that observed gender differences must be considered in the context of situational norms, gender stereotypes, and gender identity. Although each individual is unique, gender roles exert a powerful influence that should not be ignored in any attempt to understand human behavior.

GENERAL ADAPTATION SYNDROME

The General Adaptation Syndrome (GAS) is a cluster of bodily responses to severe, prolonged stressors that was described by Hans Selye. Selye observed that rats exposed to a wide variety of noxious agents exhibited a nonspecific syndrome consisting of enlargement of the adrenal cortex; shrinkage of the thymus, spleen, and lymph glands; and the appearance of ulcers in the stomach and small intestine. This response was seen in animals exposed to extreme cold and heat, intense sound or light, forced exercise, injections of various organ extracts or formalin, or a variety of other intense biological challenges to normal homeostatic function. Selye suggested that the GAS consisted of three phases of response to a stressor. The initial stage consisted of an alarm reaction during which the adrenal cortex enlarged and released large amounts of the adrenoglucocorticoid hormone cortisol into the bloodstream, the lymphatic tissues shrunk, the number of white blood cells declined, the gastrointestinal tract developed ulcers, heart rate and blood pressure increased, and the animals lost weight. During the second stage, the stage of resistance, the adrenal cortex remained enlarged, but instead of releasing cortisol, the gland retained the hormone, other tissues and physiological functions appeared relatively normal, and the body weight returned to near normal levels. With continued application of the severe stressor, according to the GAS, the animals eventually entered a third stage, called the stage of exhaustion. Here again, similar to the body's responses during the alarm reaction, substantial amounts of cortisol were released into the blood, lymphatic tissues shrank, and body weight again fell. This stage ended with the animal's death.

Selye's GAS and the research that followed from this early notion of a nonspecific response to challenges from the environment was an important idea that launched the study of biological stress. Indeed, Selye himself used the term *stress,* which he had borrowed from physics to refer to this syndrome of responses to a noxious agent. However, more recent studies of the concept of stress have broadened the definition of *stressors* to include less potent challenges to an organism's normal function, including psychological stressors. Thus, it is now clear that the GAS does not occur following all events that one would reasonably consider stressors and does not occur in all individuals. As Selye himself noted, organisms may not experience all three stages of the GAS and stressors sometimes may produce only limited features of the alarm reaction (e.g., cortisol release without gastric ulceration). Thus, the GAS does not appear to apply to any but the most intense, prolonged, and painful physical stressors. Despite these criticisms, Selye's GAS was an important concept in the history of research on stress because it suggested that in addition to the specific, finely tuned bodily changes induced by aversive physical challenges to homeostasis, there was also a more generalized bodily response elicited by any one of a diverse array of intense stressors that threatened the organism's survival.

GENETIC APPROACHES TO MEMORY

Genetic approaches fall into two general categories: forward and reverse genetics. Forward genetics is concerned with the identification of genes and the starting point is usually the identification of mutant organisms with interesting phenotypes. In reverse genetic studies, the gene is already at hand, and the goal is to define its functions. This normally involves the study of organisms with defined genetic changes. Recently, animals with genetically engineered mutations have been used to develop and test theories of memory. Additionally, novel molecular techniques have accelerated the identification of new genes required for memory.

Forward Genetics

Long before we had the ability to directly manipulate genes in animals such as flies and mice, geneticists were busy using chemical mutagens to alter genetic information in living systems (forward genetics). The goal of classical or forward genetics, which continues to be used extensively to this day, is to identify the genes critical for biological processes of interest. The idea is that study of those genes is often a critical first hint in unraveling underlying biological processes. In forward genetic screens, animals are first exposed to a mutagen—for example, the DNA-altering compound ethyl-nitroso-urea—and then mated; the progeny are screened for phenotypic changes of interest. The phenotype of a mutant is the sum total of observed biological changes caused by a genetic manipulation. Recent application of this approach in the study of mammalian circadian rhythms resulted in the identification of *clock,* a crucial link in the cascade of transcriptional events that marks molecular time in organisms as diverse as drosophila and mice (Wilsbacher & Takahashi, 1998). Other molecular components of this pathway, such as *per,* were isolated in mutagenesis screens in drosophila. By identifying novel and unexpected molecular components of biological processes of interest, forward genetics has often reshaped entire fields of research. At times, science can go in circles, obsessively chasing its own tail of half-truths. Forward genetics, in the hands of masters such as Edward Lewis (developmental mutants) and Seymor Benzer (learning mutants), has the ability to turn paradigms upside down and initiate new lines of scientific inquiry.

The First Screens for Learning and Memory Mutants

Seymor Benzer and colleagues working with drosophila at the California Institute of Technology designed the first successful screen for learning and memory mutants in the 1970s. Benzer and colleagues developed a behavioral procedure with operant and Pavlovian components. During training the flies were allowed to enter two chambers, each with a different odorant, but they only got shocked in one of the chambers. During testing approximately two thirds of the trained flies avoided the chamber with the odorant that previously had been paired with shock. With this procedure, Benzer and colleagues tested a number of *Drosophila* lines derived from flies treated with ethylmethane sulfonate (EMS). The first mutant line isolated from this screen was *dunce* (Dudai, 1988).

Remarkably, three out of the four learning and memory mutations first discovered in genetic screens in drosophila code for members of the cAMP-signaling pathway. For example, *dunce,* lacks a phosphodiesterase that degrades cAMP. In the early 1970s, Eric Kandel and his colleagues at Colombia University, while studying learning in the sea snail *Aplysia,* also uncovered evidence that cAMP signaling is critical for learning and memory (Byrne & Kandel, 1996). Importantly, these findings have recently been extended into vertebrates, where electrophysiological and behavioral studies have confirmed the critical importance of cAMP signaling to learning and memory (Silva, Kogan, et al., 1998). This is a fascinating example of convergent evidence in science, but it also serves to illustrate that genetics, like any other tool in science, is most successful when used in parallel with other approaches. Besides identifying new genes, genetics can also be used to test hypotheses about the function of cloned genes (reverse genetics).

Reverse Genetics

In classical genetics an interesting phenotype is usually the driving force behind the molecular experiments required to identify the underlying mutant gene(s). In contrast, in reverse genetics, the interesting molecular properties of a gene usually drive the generation and study of the mutant animal (hence, the word *reverse*). It is now possible to delete and add genes to many species, ranging from bacteria to mice. For example, mice can be derived with the deletion (knockouts) or overexpression (transgenics) of almost any cloned gene (collectively referred to as *transgenetic approaches*). These manipulations can involve whole genes or they can target specific domains or even single base pairs.

With classical knockout and transgenic techniques it is not possible to regulate the time and the regions affected by the mutation or transgene. However, recent techniques have circumvented these limitations. For example, the expression of the gene of interest can be regulated by gene promoters that can be controlled by exogenously provided substances, such as tetracycline derivatives (Mayford, Mansuy, et al., 1997). Alternatively, it is also possible to regulate the function of a protein of interest by fusing it with another protein that can be regulated by synthetic ligands, such as tamoxifen (Picard, 1993). For example, our laboratory has recently showed that a mutant transcription factor called $CREB^r$ can be activated in the brain at will when fused with a ligand-binding domain (LBD^m) of a modified estrogen receptor; activation of this fusion protein represses memory without affecting short-term memory or learning (Kida, Josselyn, et al., 2002). It is important to note that irrespective of the exact method used, the general idea of reverse genetic studies is that the function of a gene can be deduced from the phenotype of the mutant animal.

Knockouts, Transgenics, and Memory

The first knockout transgenic study of learning and memory analyzed mice with a targeted mutation of the α isoform of CaMKII (Grant & Silva, 1994) and showed that this kinase mediates the strengthening synapses, a process critical for learning. Many studies since then have identified more than 100 other molecules required for synaptic func-

tion and learning. These molecules include members of all of the principal signaling pathways known, including cAMP, PKC, Ras/Raf/MAPK, and so on. These studies have provided compelling evidence that the molecular mechanisms responsible for the induction and stability of synaptic changes have a critical role in the acquisition and storage of information in brain structures such as the hippocampus. This finding is of critical significance because it is the cornerstone of our understanding of the molecular and cellular basis of learning and memory. The idea that synaptic plasticity is important for learning can be traced back to luminary neuroanatomical studies by Ramon Cajal; elegant experiments in a number of species such as *Aplysia* and *Hermissenda* helped to establish it as a dominant theory of learning and memory. However, the sheer number of convergent data from transgenetic experiments in mice helped to consolidate this theory and provided a means to explore its implications and significance.

The Future of Genetic Manipulations

In the near future it will be possible to delete or modify any gene, anywhere in most organisms of interest, and at any time of choice. Additionally, more powerful forward genetic strategies will allow the isolation of entire pathways of genes involved in any neurobiological phenomenon of interest, including learning, attention, emotion, addition, and so on. Microarray techniques and other molecular cloning approaches will allow the identification of gene profiles in mutant mice. These molecular profiles will be critical to delineating the molecular changes behind the expression of a mutant phenotype. In parallel with expected advances in genetics, there will also be advances in the methods used to analyze mutants, including the use of whole-brain imaging methods such as Positron Emission Tomography (PET) and Magnetic Resonance Imaging (MRI). It is important to note that genetics allows us to reprogram the biology of organisms. The finer and more sophisticated the phenotypic and genotypic tools that we have at our disposal, the deeper we may be able to probe the magical natural programs embedded in our genes.

GENETICS AND GENERAL INTELLIGENCE

The discussions and the disputes about the contributions to general intelligence from heredity and environment have gone on for many years, but today we can reach an understanding. Progress has been made by behavioral geneticists and will be summarized. Also, a definition of *general intelligence* that is based on observable behavior will be used. It will, in genetic words, be a phenotypic definition.

The Construct of General Intelligence

The construct is derived by factor analysis, using objective methods from a wide variety of cognitive tests. By a method described by Schmid and Leiman in 1957, the factoring results in a matrix of factors that are orthogonal and hierarchical in structure. The general factor of intelligence is at the top of the hierarchy. This structure is replicable from one set of cognitive measures to another, from one sample of a population to another, and from one population to another that has had the minimum cultural exposure needed, for example, American Whites and Blacks. Note that all of the factors in the hierarchy, including the general factor, are necessarily phenotypic constructs. Factors defined by raw scores on tests do not suddenly become pure measures of hypothetical entities within the organism. The construct places the contributions of behavioral geneticists in a setting that leads to understanding. The correlates of this phenotypic score provide dependable evidence for widespread use of the score and the construct that it measures for individuals and groups.

Behavioral Genetics Data

Behavioral geneticists are using a program of correlations among different degrees of genetic resemblance of relatives

to estimate three sources of individual differences in the phenotypic trait. One of these is genetic, two are environmental. The two are called *between families* and *within families*. The nature of the between families variance is indicated by the socioeconomic status (SES) of the parents, but it is broader than traditional measures of SES. Within families depends on the abilities and motivation of the child. Children seek environmental situations that they are comfortable with. These vary from child to parent and from child to child within a family. Opportunities for such exploration are essential.

These three categories of sources of individual differences in the phenotypic trait have different properties. Genetic endowment does not change with chronological age, but some effects may appear with age. Between families makes a substantial contribution in young children, but the effects diminish as children age. Children of parents who produce the original effect do get a head start at the time of school entrance, but it shrinks with age toward zero. Within family variance substantially increases in adulthood. Increases are expected to be somewhat specialized as a result of the child's interests, genetic endowment, and the variety of opportunities the child's society and family make available. Free public education and free public libraries make important opportunities available.

The changes of the three phenotypic traits with advancing age are highly congruent with available data on the stability of individual differences in intelligence from year to year. The correlation from one year to another shows a great deal of stability of the phenotype trait but does so imperfectly. Stability increases with advancing age. Children change their positions within their own population but do so unpredictably.

Correlates of the Phenotypic Measure

There are many correlates of general intelligence, so many as to justify the name. Before proceeding to characterize them, it is necessary to correct the most common and egregious error made by psychologists and others when interpreting correlations: the automatic squaring of r to obtain r^2. The appropriate measure of effect size r is parallel to the d used for differences in means by experimental psychologists.

Properties of the Correlation Between Means

When r is used to predict the performance of individuals, the estimate of the performance score is made with a good deal of error in most circumstances. The spread of individuals around their estimated mean is given by $(1 - r^2)$. It has also been shown, however, that the correlation between the distributions of the means of X estimated from Y, r, and the means of the scores on X can be very high. The reason is that most regressions of individual differences on good measure are linear. In large Ns the correlation between means approaches 1.00. Furthermore, the slope of the regression of the means is given by the size of the r in the individual differences data. A modest r of four tenths of the difference in those data estimates a performance mean in standard score units of the actual mean from the mean of the means.

Breadth of Correlates

The generality of the correlates of general intelligence has been supplied in a lengthy list by Brand. Traits of physique, temperament, attitudes, and interests are found to be related to general intelligence. Many of these correlations are of a size similar to those for simple and discriminatory reaction time and the speed of nerve conduction. Correlations with highly speeded performance are not as high as those with correct answers. General intelligence can be defined primarily by the cognitive skills, problem solving, and information processed by a child at a particular moment in time. As stated earlier, change does take place. Intelligence is not the speed and accuracy with which data can be processed; it is the learning, storing and retrieving of data.

The generality with which an intelligence test can be used on different groups is broad but not independent of twentieth-century American and closely related cultures. It does depend on more than a minimal acquaintance with the common language. Today's Hispanic children may not be measured validly by a test heavily dependent on the use of English. Most Black children meet the minimum requirement, as do Asian children. Children with a family handicap at 6 years old may gain more than those with a family bonus by age 18, but the test is still a valid measure of phenotype at age 6.

Accuracy of the Phenotypic Test

The items of intelligence tests have been investigated looking for differential item performance (DIS). For tests that measure well, any effects appear to be small and balanced. The conclusions of regressions total scores of two groups being compared.

Data on Blacks are most extensive. There is little differences in slopes. A test valid for Whites is valid for Blacks. Not infrequently there are small differences in intercepts of the lines. Cases in which this occurs typically overpredict performance for Blacks. The amount of this overprediction is about the size that is expected when two groups with different means have scores compared that are somewhat imperfectly reliable. There is little error in concluding that a given phenotypic score on a test of general intelligence can be used to interpret accurately without knowledge of the race, White or Black, of the person who obtained it.

GENIUS

As a concept, genius is closely related to *giftedness, creativity,* and *precocity.* From F. Galton's 1869 study of eminent men onward, definitions have been problematic. Although *genius* and *giftedness* are sometimes seen as synonyms, *genius* connotes exceptionally rare and prodigious achievement, whereas *giftedness,* especially in the context of identifying and encouraging academic or creative talent, has been defined in less restrictive ways. Albert's productivity-based definition of *genius* referred to the person who "produces, over a long period . . . a large body of work that has significant influence on many [others] for many years"—work creating a "major shift" in perceptions or ideas.

Biographical studies from 1869 to the 1940s focused on historically eminent persons, reporting that they tended to come from families of high occupational level and had histories of good health and character. Little support for a link between genius and either pathology or physical frailty was found, challenging long-held notions.

Intensive studies were undertaken of living scientists, artists, and professionals recognized as unusually productive or creative. Other than high intelligence, some common features of personality, work motivation, and perceptual style characterized these subjects. This work overlapped research on creativity, expanding the concept of giftedness beyond traditional IQ-based definitions to include originality and imaginativeness. Various measures of creative ability were designed and investigated.

GERIATRIC PSYCHOLOGY

Interdisciplinary in nature and process, geriatric psychology is the science of the behavior of the aged. Geriatric psychology, with its medical, neurological, psychiatric, and physiological emphases, involves the behavioral, biological, and social sciences. The importance of cross-cultural and cross-national studies in geriatric psychology is increasingly patent in research.

Geriatric psychology is a rather new area of interest: Experimental studies of aging became a matter of concern only in the last 60 years. In 1947 George Lawton wrote comprehensively on a philosophy for maturity, proposing a bill of rights for old age. There are now delicate interpersonal situations in the multigeneration family in which the older group, conventionally defined as 65 years and over, increasingly calls for the attention, interest, and commitment of mental health workers. Geriatric psychology must be concerned with the terrors of loneliness in old age, worry about illness or shelter, anxiety over finances, or the unhappiness that results when one generation infringes on the life of another. Geriatric psychology must deal with the fact that aging is not synonymous with disease; that aging is not a state of ill health; and that a disabling, lengthy sickness is not an inevitable part of growing old. It must, however, promote understanding of the mental and emotional problems of the later years of life because accumulated physical handicaps, plus a general deterioration in bodily functions, superimpose a heavier burden on whatever emotional traumas may have developed earlier within the individual.

While the scientific body of knowledge pertaining to aging is called *gerontology,* Ignaz L. Rascher, in 1914, coined the term *geriatrics* for that branch of medicine dealing with the health problems of the aged. Rascher declared that medicine's challenge is to restore a diseased organ or tissue to a state that is normal in senility, *not* in a state that is normal in maturity; the ideal, in other words, is adding life to years rather than merely years to life.

In *Pain Management: A Practical Guide for Clinicians,* sixth edition (2002), Richard S. Weiner offers directly the most up-to-date information available on multidisciplinary pain diagnosis, treatment, and management—both traditional and alternative approaches for geriatric patients.

Geriatric psychology recognizes that the outstanding sign of aging is found in body tissues, where *stroma* (connective tissue, or nonfunctional elements) increases while *parenchyma* (functional tissue) decreases. The geriatric psychologist knows that every organ of the human body pursues its individual pattern of aging, and that, neuropsychologically, a decrease in hormones may be as important in aging as a flagging vascular system. A full understanding of the entire relationship between glands and aging still awaits full experimental findings.

The Task Panel on the Elderly of the President's Commission on Mental Health (1979) reported that the graying of America is one of the most significant demographic trends of this century. Every day 5,000 Americans join the ranks of those over 65, while only 3,600 die—a net gain of 1,400 elderly a day. The total number of older Americans is expected to increase from 23 million today to 55 million by 2030 (U.S. Census Bureau, 1977). The 75-plus age group is the fastest-growing segment of the population. Most recent census data confirm this trend.

Mental illness is more prevalent in the elderly than in younger adults. An estimated 15–25% of older persons have significant mental health problems. Psychosis increases after age 65, and even more so beyond age 75. Twenty-five percent of all reported suicides in this country are committed by elderly persons. The chronic health problems that afflict 86% of the aged, and the financial difficulties faced by many, clearly contribute to increasing stress (G. D. Co-

hen, 1977). The stresses affecting the mental health of the elderly are multiple and pervasive.

W. D. Poe and D. A. Holloway (1980, p. 147) quote Leonard Hayflick of Stanford University on population and longevity:

> . . . [I]f zero population growth can be achieved, it can be predicted that by 2025 A. D. those over 65 will number nearly 40 million and will constitute more than 20% of the total population.
>
> The inevitable consequence would be a further acceleration of current trends in which the government would be providing more health care, food, housing, recreation, and income to the elderly. Since it could safely be assumed that the proportion of those in government over 65 would also increase, the closest thing to a gerontocracy could prevail in 2025.

Frederick Sierles (1982, p. 206) wrote:

> Aging (senescence) is a gradual decline in physiological functioning as the years progress. It is debatable whether it begins with birth or in adulthood, and its causes are not known for sure. The decline in function varies in degree from individual to individual, and competence or excellence in behavior or other physiological functioning can be maintained by some at any age. For example, Vinci, Titian, Durer, Michelangelo, Voltaire, Goethe, Verdi, Renoir, and Picasso are examples of artistic genius that continued to flower in old age.

Thomas Crook and Gene D. Cohen (1981, p. 43) of the National Institute of Mental Health point out:

> Although many individuals remain physically and emotionally healthy into and beyond the seventh and eight decades of life, the prevalence of a broad range of physical and emotional disorders is increased in these years. Persons over age 65% account for a disproportionate number of visits to primary care physicians, for example, more than 30% of visits to specialists in internal medicine, and a substantial proportion of the prescriptions written for a number of drugs, including many psychotherapeutic compounds.

A basic geriatric problem of a psychological nature concerns elderly individuals who share households with kin. Charles H. Mindel's study (1979) indicated that while there has been a definite decline in the number and proportion of multigenerational households, the decline has been greater for the "young-old" (65–74) than the "old-old" (75-plus), with only slight differences in the proportion of "single" elderly males and "single" elderly females living in multigenerational families. In spite of the decline, the multigenerational household is still viable for approximately 2 million elderly persons.

K. E. Reever, J. M. Bach-Peterson, and S. H. Zarit (1979) reported on the impact of the elderly on relatives in a family constellation. The principal reason for institutionalizing cognitively impaired older persons is the caregivers' inability to continue providing help and not the severity of deficits. Feelings of burden were significantly correlated with the frequency of visits made by others but not with other variables such as the severity of cognitive impairment and frequency of memory and natural support systems as an essential part of providing services to the families of the impaired elderly. To be sure, the physical manifestations of aging are only a small part of the process of growing old. Changing attitudes, behavior, and overall personality—often the result of societal pressure—are now recognized as equally important considerations in the study of geriatric psychology.

David S. Baldwin and Jon Birtwistle in *An Atlas of Depression* (2002) present a graphical review of the diagnosis, management, and treatment of affective disorders in older populations, exploring the overlap of anxiety and the depressive syndromes in care settings.

In their *Handbook of Mental Health and Aging,* James E. Birren and R. Bruce Sloane (1980) write: "A national health problem which is most severe in terms of its prevalence and cost is a group of mental disorders and dysfunctions which are associated with aging. More important perhaps is a cost that cannot be measured or tabulated the loss of human potential and of the affected person's capacity for adaptation and ability to contribute to human welfare."

Geriatric psychology also concerns itself experimentally and theoretically with the signs and symptoms of disease processes. Widespread inflammation, muscular rigidity, cough, pain, and fever in the elderly are not minor but acute processes. Senile persons cannot bear extremes such as heat, cold, overeating, starvation, and dehydration. The older individual has accumulated many scars from the hazards of life: injurious habits, poor nutrition, intoxications, infections, and actual injuries, including the psychological traumas incident to a long life.

Steven Steury and Marie L. Blank (1981, p. 105), writing on retirement, state:

> In contrast to the popular view of the post-menopausal, emptynest phase of a woman's life, it is typically experienced as a productive period with increased levels of satisfaction.
>
> Retirement in men is often considered an equivalent of menopause and may be viewed as marking the end of a productive life. Retirement is a new phenomenon in the history of man. In preindustrial societies men continued to work until poor health or death intervened. Some persons view work and satisfactions derived from work—apart from the income itself—as the ralson d'etre for men, much as they do childbearing for women.
>
> For many men, however, work is not the central life concern by middle age. Its meaning varies substantially by occupational level. For many men retirement is not feared but anticipated.

Another important aspect of geriatric psychology is the sexuality of the older person. Katie Ludeman (1981) reports that research refutes the pervasive cultural myth of asexual age. Men and women continue to be physiologically capable of sexual functioning, although in most older persons

interest in sexual activity and actual performance decline with age. Older men are more interested in sex and more active sexually than older women.

In *Innovative Approaches to Health Psychology* (2002), edited by Margaret A. Chesney and Michael H. Antoni, it is pointed out that in our era of vaccinations, angioplasty, and gene therapy, there is the ongoing need for behavioral change in improving health on all age levels.

D. L. Parron, F. Solomon, and J. Rodin (1981) emphasize the need to direct the behavioral sciences toward a wider range of health problems than the mental health issues with which they have traditionally been concerned, to link the biomedical and behavioral sciences, and to stimulate interdisciplinary clinical and basic research. They point out that new research initiatives should be undertaken with respect to the changing vulnerabilities of the elderly to disease, the relationship of attitudes and beliefs regarding health and illness that influence the health care provider to the elderly, and the relationship of the health care provider to the elderly patient.

Appropriate attention should be given by mental health practitioners to the immunologic status of the elderly, for example, the impact of behavioral processes of adaptation on immune function, the impact of age-related changes in immunologic competence on behavior, and the role of the immune system in mediating relationships between behavioral processes of adaptation and the maintenance of health and the development of disease.

One of the major problems in the work of the geriatric psychologist is that of chronic, degenerative diseases, which include gout, arthritis, arteriosclerosis, and nutritional disorders (e.g., diabetes, anemia, and gonadal deficiency). Most of the disorders of old age are of doubtful etiology. They usually arise from factors within the patient, are highly variable, and are in operation years before they are overtly manifested. Unless and until the causative factors are unequivocally established, geriatric psychology must aim at *control* rather than cure and at *prevention* through better supervision and living. James A. Brussel (1967), writing on environmental stress in later years, quotes Claude Bernard, the father of modern physiology: "Health comes from harmony between the external environment and the internal milieu." This implies that geriatrical and gerontological knowledge, if it is to be truly scientific, must embrace all aspects of the process of aging.

Herbert Pardes wrote: "It is the challenge, and often the quandary, of behavioral scientists to assimilate a vast variety of influences and forces into a coherent portrayal of the whole person. A comprehensive model for studying and understanding the process of human development across the lifespan is essential for progress in all areas of understanding mental health and illness" (Greenspan & Pollock, 1981).

Christopher Foote and Christine Stanners in their *An Integrated System of Care for Older People* (2002) express the thesis for a multiagency approach to the support of older people, including coordinates of medical, social, and community services.

W. A. Knaus and others (1982) refer to the need for improved systematic data collection on acute and chronic health status to help make the intricate relationships among age, intensive care, and outcome easier to investigate and thereby improve.

The keynote in geriatric psychology is *individualization.* Each elderly person must be separately assessed and inventoried. The changes psychologically produced by old age are many: changes in emotional reactions, in intellectual functioning, response to stress, immunity, biochemical equilibrium, metabolism, structure, and so forth. In fact, recognition of "abnormal" mental and emotional features in persons of advanced years still remains one of the real perplexities of medical practice. Nowhere in the fields of psychiatry, neurology, and geriatric psychology are holistic principles of practice more meaningful than in treating geriatric individuals, for the aged person's mental condition will always be complicated by organic disorders of some kind.

Studies of health behavior in the elderly must take into account the social conditions as well as the underlying physical and psychological changes that occur with age. These changes function as a substrate for the influence of age and the presentation of disease, response to treatment, and complications that ensue. The same is true for the study of alcohol and drug use in the elderly. Of particular interest in both domains is the variability of physiological changes within and among individuals. Understanding the relationship among central nervous system, endocrine, and immune function may help in identifying one of the bases for this variability.

Research is needed to determine how adaptation to environmental situations may be interrelated with psychological defenses, coping, and social supports because these factors affect health and disease in older persons. Geriatric psychologists should look at specific components of the immune response and at substances such as thymic factors—especially important because they change with aging—that have powerful influences on immune function. Many of the important questions concerning the effect of aging on the interaction of health and behavior demand ongoing multidisciplinary research.

GERONTOLOGY

Increasing life expectancy has led to remarkable growth in the older adult population. According to the 2000 U.S. Census, 35 million older Americans, or 12.4% of the U.S. population, is over the age of 65. The over-85 age group includes 4.2 million Americans, the fastest growing age group in the United States. With the aging of the baby boom cohort, there will be 70.3 million Americans over age 65 in the year 2030. The rapidly growing older population and the significant impact of aging on physical, psychological, and social functioning suggest that knowledge about gerontology (normal aging) and geriatrics (clinical aging) will become vital for researchers, clinicians, and policy makers.

Successful Aging, Normal Aging, and Age Related Disease

Gerontologists distinguish between age-related disease, normal aging (typical changes without such disease), and successful aging (aging under optimal conditions). Each age cohort experiences a unique set of historical events, socialization, and education that shapes the experience of aging. Future cohorts of older adults are likely to have higher educational attainment, higher rates of Mood and Substance Abuse Disorders, and more favorable attitudes about mental health services than today's cohort of older persons. Societal changes also produce different contexts for aging, such as changing expectations about retirement and the roles of women. Therefore, descriptions of the characteristics and problems of older persons should be examined with some caution, as the older adults of the future may have some very different challenges and resources than are seen at present.

Aging increases risk for many disabling chronic diseases, including osteoarthritis, coronary heart disease, cancer, stroke, and Alzheimer's disease. Even in the absence of significant disease, normal aging is associated with loss of reserve capacity in systems including cardiovascular, pulmonary, and muskuloskeletal systems. This loss of reserve capacity leads to losses of strength, increases in body fat, and poorer aerobic capacity in the absence of sustained efforts to maintain fitness, which in turn increases risk for loss of functioning and independence, especially with illness or trauma. Recent studies of successful aging have shown that older adults who engage in aerobic and strength training can make considerable gains in capacity that are important in maintaining daily functioning. However, even world-class senior athletes, who may be genetically gifted and trained to optimal capacity, do not perform at the level of younger athletes.

In normal aging, many cognitive functions are well maintained including crystallized intelligence (vocabulary, overlearned information and behaviors, reasoning and judgment), immediate memory, and recognition memory.

Aging is associated with declines in fluid intelligence, or the ability to rapidly solve novel problems; slowing of cognitive functions; and declines in memory, especially difficult tasks requiring the use of free recall. However, normal age-related changes in cognition may be of minimal importance in the daily functioning of older persons unless they remain active in extremely demanding occupations. Most older persons find successful ways of compensating for these age changes or select activities that suit the changes in their intellectual skills, such as the scientist who transitions into mentoring and administration.

Aging, Stress, and Mental Disorders

Aging is associated with increased risk for a number of important stressful life events and chronic strains, including declines in health, death of spouse or significant others, and caregiving for impaired family members. However, common conceptions of late-life as generally stressful or unpleasant are incorrect. For example, recent studies of retirement show no negative effects on health or psychological functioning once preretirement physical and emotional functioning are considered. Older adults have lower rates of some stressful life events than younger persons because of their retirement status. Older persons are also often found to cope as successfully with problems as younger persons, and in some cases better, in part due to their prior experience with adversity and the fact that certain problems (such as spousal bereavement) are normative in late life.

The present cohort of older persons has lower rates of major depression, substance abuse, and some other mental disorders than younger cohorts. Older persons are at increased risk for a number of mental disorders, including the dementias (of which Alzheimer's disease is most common) and subsyndromal depressive and anxiety disorders. Future projections suggest we will see increased prevalence of late-life mental disorders when the baby boom cohort reaches advanced age. Mental disorder in older adults is distinct in that it is often comorbid with multiple physical disorders and complicating social factors. Older persons are often taking multiple medications and seeing multiple health care providers. These changes mean that mental health or behavioral health services should be carefully coordinated with medical and social services, ideally through multidisciplinary teams.

Clinical Assessment and Intervention

Psychological assessment of older adults should include attention to medical, social, and cultural issues, and clinicians should assure that assessment instruments are culturally sensitive and appropriately normed for older populations. Without attention to differences in educational attainment, older adults may be inappropriately diagnosed with cognitive and mental disorders. Comorbid medical problems may complicate the assessment process as well. Special measures designed to provide brief and valid assessments of common problems in older adults include the Geriatric Depression Scale, Mini-Mental State Exam, and Mattis Dementia Rating Scale.

Contrary to common conceptions, research has demonstrated the effectiveness of a variety of psychological interventions for older persons and their family caregivers for problems such as geriatric depression, family caregiver distress, managing incontinence, and reducing disruptive behaviors in patients with dementia. Interventions for older adults should be tailored to their values and perspectives. For example, the current cohort of older persons tends to fear psychiatric stigma and prefer treatment in medical settings. Innovative approaches that integrate psychological services into primary care and other medical settings hold considerable promise for reaching older adults that would resist referral to traditional psychiatric settings.

Future Issues

Given the projected growth of the older population, mental health professionals should attend to several important issues. First, all professionals providing mental health services to older adults need to receive basic education and training in geriatrics and gerontology with supervised practicum in order to meet the unique and various mental health services needs of future cohorts of older adults. Due to increased rates of disorders in younger cohorts and the aging of the baby boom population, we must also develop a larger cadre of geriatric specialists in all professions to work with patients with complex problems, conduct research, and train other professionals in the field of aging.

The 2000 U.S. Census data suggest that 25.4% of the elderly population in 2030 will be members of racial and ethnic minority groups. Increasing life expectancy among racial and ethnic minority groups means an increasingly diverse aging population and thus, interventions for older adults should be developed and provided in culturally sensitive and appropriate ways. Clinicians should consider factors such as cohort-specific discrimination and different values concerning caregiving and mental health issues held among different ethnic minority elderly groups.

Issues regarding reimbursement and public education need more attention as well. While Medicare is the primary insurer of older adults it requires higher copays for mental health than for other services. At the same time, many older adults are not aware that psychological services are covered under Medicare. Thus, it is important that the public is educated more about aging and mental health issues.

Our society is poorly prepared to provide for the growing numbers of older adults who will be increasingly diverse in their demographic and sociocultural characteristics and will also need medical, psychological, social, and long-term care services. Public policy must evolve to find ways to distribute resources to the special needs of older

adults and their families while attending to issues of generational equity.

GESTALT PSYCHOLOGY

Early in the twentieth century, Gestalt psychology came about as an amendment to the traditional method of scientific analysis. The accepted way of analyzing a complex phenomenon scientifically had been that of describing the parts and arriving at the whole by adding up the descriptions thus obtained. Recent developments in biology, psychology, and sociology had begun to suggest, however, that such a procedure could not do justice to phenomena that are field processes—entities made up of interacting forces. The need for a revision was felt first in the life sciences, but inevitably extended to the physical sciences as well. Gestalt psychology thus became a component of a more broadly conceived Gestalt theory concerning scientific method in general.

This extension into the physical sciences became an integral aspect of the Gestalt approach for two reasons. First, many psychological phenomena, especially those in perception, could be described but not explained by what was observable at the level of conscious experience. It was possible to determine by laws or rules which conditions led to which consequences, but the only way to indicate the causes of such happenings was by reference to the physiological counterpart of the observed phenomena.

This procedure, then, implied a parallelism between psychological experience and correlated processes in the nervous system. The laws governing the functioning of the brain and, by extension, the physical universe in general, were assumed to be reflected in mental activity as well. Such a view—a second reason for Gestalt psychologists to stress the link with the physical sciences—made it possible to coordinate the functioning of the mind with the organic and inorganic world as a whole.

In textbooks of psychology the Gestalt approach is often exemplified by the "rules of grouping." Although easily reconciled with traditional analysis, these rules were presented by Wertheimer in preparation of what might be called a Copernican switch from a mere linking of elements "from below" to a primary concern "from above" with the total structure of the phenomenon.

In his paper "Laws of organization in perceptual forms," Wertheimer showed that the formation of Gestalt patterns is governed by a supreme principle which he referred to as the tendency toward the "good Gestalt" or the *Prägnanz* principle meant to describe a strictly objective tendency toward the greatest simplicity and regularity.

This tendency toward the simplest structure available under given circumstances or, to use a related criterion, toward the lowest available level of tension, has been of great explanatory value, especially in the exploration of sensory perception. Nevertheless, the simplicity principle alone was insufficient to account for perceptual Gestalten. If it ruled unopposed, it would reduce percepts to an amorphous homogeneity, to the limiting case of structure. What was needed was a counteragent, an anabolic tendency that offered constraints to the organizing forces in the field. In perception, the principal supplier of such constraints was the world of stimuli impinging on the receptor organs of the senses, especially those of vision, hearing, and touch.

At the retinal level, little if any of the Gestalt organization takes place. (The more recently discovered receptive fields in the retinae or the cerebral cortex of animals do not activate Gestalt processes.) At the higher levels of the visual apparatus, the stimulus configuration constrains the physiological field process, which is determined first of all by the tendency toward simplest structure (i.e., the physiological counterpart of the percept assumes the simplest structure compatible with the stimulus situation). A Gestalt has come about through the interaction between the stimulus configuration and the organizing powers of the visual field.

It is this interaction between tension-enhancing and tension-reducing forces that brings about the state of what Wertheimer called *Prägnanz*.

Gestalt structures vary all the way on a scale extending between two hypothetical poles. At the one extreme, there would be the state of total interaction. At the other extreme, the parts of a whole would be totally independent of one another, so that what happened at one place in the constellation would have no effect on the remainder.

Interaction in a Gestalt context is the very opposite of the functioning of machines, in which, in Köhler's formulation, the form of action in the system is entirely prescribed by the constraint. All action takes place along preordained channels. Machines can serve also as illustrative models for the networks of defined concepts that constitute intellectual reasoning, such as scientific theories. It must be made clear that although field processes in psychology and elsewhere must be understood as Gestalten, a scientific statement itself, by its very nature, can never be a Gestalt. Gestalten exist in perception, in mental imagery, in the dynamics of the human personality, in physiological and physical states of interaction, but they can be conceptualized only through networks of relations. The validity of the scientific description depends on how faithful an equivalent it offers, with its own means, of the Gestalt structures it undertakes to match.

The Gestalt approach requires that the subdivision of a whole into its components be effected in strict obedience to the cleavings inherent in the given structure itself. As a

practical consequence, the range of a problem singled out for investigation cannot be arbitrarily staked out, but depends strictly on what is relevant for the processes under scrutiny. To discover the proper range of a problem is nearly tantamount to finding its solution.

Gestalt structure extends in the time dimension as readily as in the space dimensions, and the principles governing time and space are similar. The Gestalt analyses of spatial relations have had very little competition, but when it came to sequences in time, Gestalt psychology had to cope with a powerful tradition that explained all temporal connections by the laws of association. In its original form—in Aristotle—associative connections were based on something either similar or contrary to what we seek, or else on that which was contiguous with it. Such criteria were compatible with the Gestalt effort to derive connection from structural organization. When, however, it was asserted that associations come about by mere frequency of occurrence, Gestalt psychologists raised objections. A doctrine according to which anything could become associated with anything if it had been its neighbor often enough replaced meaningful belonging with a whimsical subjectivity.

Gestalt psychologists denounced conditioning by mere repetition as the lowest form of learning and opposed it with learning through understanding. Productive learning was now asserted to occur when a person or animal acted according to the demands of a given structure. Effective learning could come about only when the learner perceived the connections among the decisive elements of a given situation by what was called *insight*.

A decisive difference between the purely perceptual grasp of a given structure and a *problem situation* in the more particular sense of the term should be mentioned here. In simple perception, problem solving is limited to finding the structure inherent in the stimulus data. A harder task challenges the observer when a situation presents itself as organized in a way that conceals the connections needed for a solution. Restructuring may consist in merely looking at the situation differently or may require an actual rearrangement of the components.

The restructuring of a Gestalt is an eminently dynamic activity of field forces, but so is all structuring in the first place. In fact, a structure by definition never ceases to be a constellation of forces. Just as an apparently stable social pattern such as a family group never ceases to be a more or less balanced arrangement of various motivational tendencies, so a visual pattern presents to the sensitive eye a system of variously directed vectors that keep one another in balance. This reflection of the corresponding physiological field forces in experience is what Gestalt psychologists describe as perceptual expression. Expressive qualities are authentic and objective properties of all percepts. They can even be called the primary qualities conveyed by perceptual shape, size, movement, intensity, timbre, and so on.

Perhaps the most characteristic aspect of the Gestalt view is its profound respect for the "givenness" of the world as an objectively existing cosmos held together by law and order. It is a view that leads to a theory of value based on the criterion of objective requirement. Whether it be the irrational pressure of an instinct or the demands of the categorical imperative, value in Gestalt psychology is considered a field force—one that by no means issues always from the ego needs of the person who is doing the valuing. Gestalt psychology is therefore in strong philosophical opposition to a worldview that describes values as purely subjective and arbitrary, and therefore as idiosyncrasies to be excluded from the scientific image of the world.

GESTALT THERAPY

Origins

Gestalt therapy is an existential and phenomenological approach, emphasizing the principles of present-centered awareness and immediate experience. To discover how one blocks one's flow of awareness and aliveness, the individual in therapy is directed to fully experience current thoughts, feelings, and body sensations. Gestalt therapy was developed by Frederick S. (Fritz) Perls, M.D., who was trained in classical Freudian psychoanalysis. Perls's broad interests in existentialism, Eastern religions, and Gestalt psychology led him away from the Freudian viewpoint toward his own theory and method of therapy. Perls saw the human being as a unified organism, an integration of mental, physical, emotional, and sensory processes expressed in the present moment. Wulf (1998) notes that together with Perls, two other cofounders, Laura Perls and Paul Goodman, also were instrumental in creating the new synthesis.

Gestalt is a German word with no exact English equivalent. It means a configuration or whole, an entity which is more than the sum of its parts. In his first book, Perls presented the preliminary outlines of his approach (Perls, 1947). Later works elaborated and extended these early formulations (Perls, 1969; Perls, 1973; Perls, Hefferline, & Goodman, 1951).

Major Theoretical Concepts

Gestalt theory suggests that a continuing flow of needs and wishes comes into awareness, each of which can be thought of as a Gestalt, a figure or focus which emerges out of an undifferentiated background of experience. In healthy functioning, the organism mobilizes to meet each need, making contact with aspects of the environment appropriate to need satisfaction. For this self-regulating process to func-

tion, it is essential that the organism has sufficient *awareness*—that is, be in touch with thoughts, feelings, and sensations as they occur from moment to moment.

Perls emphasized the importance of accepting responsibility for one's own behavior. Instead of denying, blaming, projecting, and displacing responsibility for one's experience, the individual is encouraged to accept thoughts, feelings, and actions as parts of the self. Another key concept is *unfinished business,* incomplete situations from the past, accompanied by unexpressed feelings never fully experienced or discharged. Unfinished business can be resolved by reenacting (either directly or in fantasy) the original situation and allowing the associated effect to be experienced and expressed.

Therapeutic Goals and Role of the Therapist

The Gestalt therapist assists the patient to achieve greater self-acceptance, to assume more personal responsibility, to reintegrate disowned or split-off aspects of personality, and to be more authentic and less manipulative in relating to others.

The Gestalt therapist brings his or her own individuality into the encounter and takes responsibility for being present in a direct, spontaneous, and self-disclosing manner. Perls summed up the relationship between therapist and patient succinctly in his dictum, "I and Thou, Here and Now" (Yontef, 1993, p. 66).

Techniques of Gestalt Therapy

Gestalt therapists have described a variety of techniques to sharpen direct experience, heighten conflicts and polarities, foster freer expression, or to bring into awareness blocks and avoidance mechanisms. *Continuum of awareness* is a technique which encourages the patient to focus on the now, the ever-shifting midpoint of experience. The Gestalt therapist avoids "why" questions which encourage theorizing, rationalizing, and justifying. Instead, the therapist encourages the patient to "stay with" whatever is in the foreground and bring full awareness to the experience. The resolution of an unpleasant situation lies in experiencing it fully, not trying to avoid it.

In Gestalt therapy as practiced by Fritz Perls, *taking the hot seat* indicated a person's willingness to engage with the therapist. In this case the *hot seat* was a chair facing the therapist. An additional empty chair next to the patient might be used to imagine the presence of a significant other or disowned part of self for the purpose of initiating a dialogue. As the interplay between these conflicting parts is heightened and more fully experienced, integration through greater self-acceptance becomes possible. In the Gestalt method of *dream-work,* each dream is thought to contain an existential message—an expression of aspects of the dreamer's present state of being. By becoming every object and character in the dream (both animate and inanimate), the dreamer can identify with and thereby reown projections, conflicts, and unfinished situations reflected in the dream.

Applications of Gestalt Therapy

As originally practiced by Fritz Perls, Gestalt therapy was primarily an individual form of treatment. Other Gestaltists have applied the principles to group therapy (e.g., Glass, 1972; Feder & Ronall, 1980). Going beyond Perls's unique personal style of therapy, the work has been extended to a broad spectrum of client populations. Brown (1975) and Oaklander (1978) have described Gestalt work with children and adolescents. Gestalt family therapy is presented in the works of Kempler (1981) and Resnikoff (1995). Herman and Korenich's applications to management (1977) further increased the breadth and scope of Gestalt theory and practice.

Evaluation and Current Status

Gestalt therapy at its best can be energizing and enlivening through its emphasis on direct contact, expressiveness, focus on feelings, and minimal theorizing and interpreting. Critics, however, have pointed out that this approach can be technique-dependent, overly confrontive, and suitable only to well-motivated, verbal clients.

In the 50 years since its inception, Gestalt therapy has undergone considerable evolution. Yontef (1999) describes a growing movement toward a more relational trend in Gestalt therapy characterized by increased support and greater gender and culture sensitivity and away from the confrontation, catharsis, and dramatic emphases of the 1960s and 1970s. Gestalt therapy has become truly international with active practioners, institutes, training centers, and university-based programs throughout the United States and in many other countries.

Diversity in therapeutic styles, adaptations to varied client populations, and a burgeoning literature all point to Gestalt therapy's continuing vitality and development, as it finds its place in the mainstream of contemporary psychotherapy.

GLANDS AND BEHAVIOR

Glands may be classified as either exocrine or endocrine. Exocrine glands have ducts. Their products perform their functions in the immediate vicinity of the secreting gland, but outside the tissues of the body, although this may mean within the mouth or gastrointestinal tract. Sweat glands, salivary glands, and the exocrine pancreas, which secretes peptides involved in digestion, are examples. They have little direct influence on behavior. Endocrine, or ductless, glands secrete their products into the bloodstream and exert their effect on organs distant from the secreting gland. Several can produce profound direct effects on (1) maintenance of homeostasis; (2) modulation of emotional behaviors, especially those related to stress; and (3) sexual and gender-related behaviors.

There are six endocrine glands, and two of them have structurally and functionally distinct divisions. The pituitary, one of these latter two glands also known as the hypophysis, lies at the base of the brain and is connected to the hypothalamus by the infundibular or pituitary stalk. The anterior division of the pituitary is significantly larger than the posterior division and is called the adenohypophysis. The adenohypophysis is truly a gland and secretes growth hormone, adrenocorticotropic hormone, thyroid-stimulating hormone, prolactin, and the gonadotropins. Levels of hormones secreted by the adenohypophysis are controlled by the hypothalamus through its connections to the median eminence where axons from the cells of the parvicellular system of the hypothalamus release factors that either stimulate or inhibit release of anterior pituitary hormones.

The posterior division of the pituitary, the neurohypophysis, receives direct innervation from the hypothalamic magnocellular neurosecretory system. The cells of origin of the magnocellular neurosecretory system are located in the supraoptic and paraventricular nuclei of the hypothalamus, and they send axons to the neurohypophysis. The terminals of these axons release oxytocin and vasopressin that enter the bloodstream.

The adrenal gland also has two parts. Its outside is the cortex. Releasing hormones from the pituitary stimulate cells of the adrenal cortex to release either mineralocorticoids or glucocorticoids. Mineralocorticoids such as aldosterone work on the kidney to enable conservation of salt and water. Glucocorticoids are involved in the body's response to stress. The inside of the adrenal gland is the medulla. Its cells are the target of preganglionic sympathetic axons from the spinal cord and release adrenalin and noradrenalin into the bloodstream.

The testis of the male and the ovaries of the female comprise the gonads. Both the female and male gonads secrete estrogen, progesterone, and testosterone. The relative amounts of these hormones determine the sexual characteristics that distinguish the two genders.

The remaining endocrine glands are the pancreas, thyroid, and parathyroid. The endocrine pancreas secretes insulin necessary for glucose and fats to enter cells so that the cells can use them for energy or, in the case of fat cells, store them. The thyroid gland secretes thyroxin, which regulates metabolic rate and protein synthesis by cells throughout the body. The parathyroid secretes a hormone involved in the regulation of calcium concentration in blood. This gland has little direct influence on behavior.

The activity of virtually all endocrine glands, with the exception of the adrenal medulla, is directly modulated by hormones released from the pituitary, whereas the pituitary is regulated by the hypothalamus. Although the adrenal medulla receives direct input from the sympathetic division of the autonomic nervous system, even the release of adrenalin and noradrenalin by this gland is influenced by the hypothalamus because of its ability to control the autonomic nervous system. Any discussion of the role of glands in the regulation of behavior must include the hypothalamus.

Hormonal Influences on Homeostatic Mechanisms

The concept of homeostatic mechanism refers to any activity or group of activities designed to maintain a cell, an organ, or an entire organism in a steady state optimal for survival known as homeostasis. At the cellular level, an ex-

ample of such an activity would be activation of the sodium-potassium pump to regain intracellular and extracellular concentrations of these two ions appropriate for the resting membrane. Eating and drinking behaviors are examples of homeostatic mechanisms at the level of the whole organism. Neural and hormonal systems are involved in maintaining organism homeostasis in mammals.

To maintain homeostasis, the body requires a variety of substances such as vitamins, minerals, trace elements, fats, carbohydrates, and proteins. If excess amounts of any of these substances are present in the circulation, they may be either excreted or stored. If too small an amount is present, it is necessary, in most cases, to ingest the missing substance. However, inadequate levels of vitamins, minerals, and trace elements (with the possible exception of salt) do not induce hunger. Hunger and consequent behaviors related to finding food and eating are induced by low levels of carbohydrates, fats, and possibly proteins.

The endocrine pancreas is the gland involved in the modulation of feeding. The islands of Langerhans scattered throughout the pancreas compose its endocrine division. Three different cell types within the islands of Langerhans secrete three hormones involved in regulating the availability of glucose to cells. These are glucagon, which raises blood glucose; insulin, which lowers the level of blood glucose by binding with cell membranes throughout the body and brain to permit entry of glucose into the cell; and somatostatin, which appears to regulate the release of glucagon and insulin. Insulin is the hormone of the endocrine pancreas most directly related to eating behavior.

Insulin is secreted in response to increased levels of blood glucose. This may occur after a meal or if glucagon is released and circulating glucose increases. Increased insulin levels cause glucose to enter cells more quickly where it is either used for fuel or, in the case of fat cells, is converted to triglycerides and stored. Blood glucose levels then drop. Data support the contention that hunger and eating are initiated when nutrient levels, especially glucose levels, decrease in the blood. Thus a high insulin level could lead to hunger because it decreases blood glucose. Furthermore, insulin levels can be influenced by the hypothalamus, and disruption of this control by hypothalamic lesions may explain some of the effects of such lesions on eating behavior and body weight.

The dorsal motor nucleus of the vagus nerve provides input from the brain to the pancreas. Neurons of the lateral hypothalamus send input to the dorsal motor nucleus, and stimulation of the lateral hypothalamus increases circulating insulin levels. Neurons in the lateral hypothalamus appear to be sensitive to changes in blood glucose use, either because they have glucoreceptors themselves or receive neural feedback from liver glucoreceptors. Bilateral destruction of the lateral hypothalamus produces an animal that will not eat and will starve unless it is carefully nursed back to health. It has been suggested that this effect is due to loss of lateral hypothalamic stimulation of the vagal nucleus, which leads to increased levels of insulin. Thus an animal without its lateral hypothalamus has continued levels of low insulin and low rates of glucose utilization. Therefore, its brain does not sense that it is hungry, and eating is not initiated. This is, of course, not a complete account of the neural control of hunger and eating, nor is it the only mechanism by which the lateral hypothalamus influences eating, but it does provide the first example of how the hypothalamus and a product of an endocrine gland interact to modify homeostatic behavior.

A second example is provided by drinking, which is part of a homeostatic mechanism designed to regulate body water content, salt concentration, and blood pressure. When blood volume decreases as a consequence of water loss, as might occur during heavy exercise that results in excessive sweating, blood volume drops, and blood flow slows down. This decrease in blood flow is sensed by the kidney, which responds by releasing renin, which in turn is converted to angiotensin in the bloodstream. Angiotensin does two things: It stimulates the adrenal cortex to release the hormone aldosterone, which stimulates the kidney to return sodium to the bloodstream. As the sodium is returned to the bloodstream, water is carried with it, and blood volume is partially restored by this mechanism. Angiotensin also stimulates the subfornical organ in the brain. Neurons in the subfornical organ in turn stimulate the circuitry in the medial preoptic area that mediates drinking behavior via connections to the midbrain. In addition, loss of extracellular water stimulates osmoreceptive neurons in the nucleus circularis of the hypothalamus that stimulate the supraoptic nucleus. This causes antidiuretic hormone (ADH) to be released from the posterior pituitary. ADH causes the kidney to concentrate urine and return water to the bloodstream. Therefore, thirst and drinking are also homeostatic mechanisms greatly influenced by glands.

Hormonal Responses to Emotional Stress

The two principal kinds of emotional behavior influenced by endocrine glands are those related to stress and those related to gender-specific sexual behavior. Gender-specific behaviors are not only those behavioral patterns involved in mating and care of the young, but also acts such as intermale aggression not directly involved in reproduction of the species. Certain of the gonadotropins are necessary to organize the development of the neuronal circuits that underlie these behaviors.

Terms used to classify emotions generally include happiness, love, grief, guilt, and joy. However, most of these are impossible to define with sufficient operational rigor to permit scientific study, especially when animal models are used to unravel the neural and endocrine contributions to the emotional state and accompanying behavior. This is because these categories of emotion have not been constructed and refined from empirical observation. Rather, they are words taken from everyday language that describe either

the speaker's introspective state or the internal state of another individual inferred from that individual's behavior. Therefore, the contribution of the neuroendocrine systems to many emotional states commonly described in everyday terms is not known. However, the relationship between stress and the neuroendocrine system is well established, and this relationship may be extended to the states of fear and anxiety.

Fear may be usefully regarded as a response to a specific stimulus present in the environment, whereas anxiety is an anticipatory response to a possible threatening event. Fear, then, is generally a shorter-lived state, whereas anxiety may be chronic and generalize to the degree to which it is not bound to a specific stimulus. However, both of these states produce similar endocrine responses. The simplest of these responses involves discharge from the sympathetic neurons located in the spinal cord. The axons of the sympathetic neurons terminate on visceral organs, including arteries. Their activity during periods of stress increases blood pressure, heart and respiratory rates, and the release of liver glucose stores, while gastrointestinal motility is decreased. In addition, sympathetic activation of the adrenal medulla increases the release of adrenalin and noradrenalin into the bloodstream.

The adrenal cortex also is involved in response to either acute (fear) or chronic (anxiety) stress. However, the adrenal cortex is not directly activated by the sympathetic nervous system. As noted earlier, the adrenal cortex is activated by adrenocorticotropic hormone (ACTH). ACTH is released from the adenohypophysis (anterior pituitary) and stimulates the adrenal cortex to release glucocorticoids (cortisol, cortisone, and corticosterone). The glucocorticoids increase cardiac and vascular muscle tone, enhance the release of nutrients into the blood, decrease inflammation, and inhibit protein synthesis. The release of ACTH by the anterior pituitary is controlled by the hypothalamic hormone, corticotropin-releasing factor (CRF). CRF is manufactured by neurons in the paraventricular nucleus of the hypothalamus and is transported down the axons of these neurons and released into the portal circulation of the adenohypophysis where it stimulates release of ACTH. The paraventricular nucleus is strongly influenced by structures in the limbic system, such as the amygdala, that are involved in modulation of fear responses. The secretion of glucocorticoids by the adrenal cortex is closely linked to parts of the brain involved in elaboration of fear states and intensification of behaviors that accompany them.

Activation of both the sympathetic-adrenal medullary response and the hypothalamic-pituitary-adrenal cortical response are obviously adaptive in the face of immediate, comparatively short-term threat. These responses help the organism to fight or flee. However, as described by Selye, continual activation of these systems by chronic stress can lead to serious consequences for health. Selye referred to the changes produced by long-term stress as the general adaptation syndrome (GAS) and divided it into three stages. The first stage is the alarm reaction during which the body significantly increases the production and release of the stress hormones. This first stage lasts only a few hours, but the second stage, resistance, may continue for days or weeks. During this stage, blood levels of adrenalin, noradrenalin, and the glucocorticoids remain high. The final stage is exhaustion when the body can no longer respond to the stress.

GAS may be brought about by any stressful situation, including chronic physical stress (e.g., from exposure to extreme cold or in times of real physical danger), but it also may occur as a result of continual psychological stress. As originally described by Selye, the physical correlates of GAS include enlarged adrenal glands, with a marked increased in size of the adrenal cortex as its cells respond to the actions of ACTH and attempt to produce ever larger quantities of the glucocorticoids, as well as a shrunken thymus, weight loss, and gastric ulcers. Gastric ulcers are caused by chronic decrease in blood flow to the gut. Substantial rates of blood flow are necessary for maintenance of the mucosal lining that protects the stomach from the digestive acids. As a consequence of chronic activation of the body's stress response, the gut's blood flow is so decreased that its mucosal lining deteriorates, and the stomach's hydrochloric acid produces ulcers.

The cause of the shrinkage of the thymus noted in GAS is not known. The thymus is responsible for producing many of the lymphocytes (key cells in the immunologic defense of the body from infection), and chronic stress decreases the ability of the immune system to respond. The mechanism for stress-induced reduction in immune responsiveness is known and involves the increased amounts of circulating glucocorticoids present during stress.

Enhanced levels of glucocorticoids decrease protein synthesis. As a short-term part of a response to threat this is useful because it conserves metabolic energy. However, the decreased protein synthesis extends to those proteins that form the receptors on cells that recognize foreign elements in the blood. These receptors constitute antibodies, and the cells are the white blood cells (leukocytes), including the lymphocytes. During stress, production of both the antibody receptors and the cells that carry these receptors decreases. Prolonged periods of stress results in immunosuppression and increased susceptibility to infectious disease and the development of cancer.

Abnormally high levels of the glucocorticoid cortisol also have been found in 40–60% of depressed patients and is known to be caused by enhanced secretion of CRF by the hypothalamus. The hypersecretion of CRF by the hypothalamus is probably a specific effect of the general dysfunction of the ascending aminergic neurotransmitter systems (dopamine, norepinephrine, and serotonin) thought to be the biological cause of depression.

The overall effect of activation of the neuroendocrine systems involved in response to stress is to produce a state of enhanced readiness for physical action without neces-

sarily activating specific neural circuits that produce directed behaviors. Although such activation may be beneficial for survival in the face of real threat, prolonged activation of these systems is detrimental to health.

Gender-Specific Behavior

Gonadal hormones exert effects on the nervous system and consequently on behavior that depend on the stage of development of the organism. During critical developmental periods, gonadal hormones produce permanent changes in the organization of neuronal circuitry that results in sexual differentiation of behavior. In the adult, gonadal hormones can activate gender-typical behaviors, but the behaviors do not persist in the absence of the hormone, and structural changes in the brain are not produced.

One gene determines whether the fetal animal or human will differentiate into a male or a female adult. Sexual dimorphism includes obvious body characteristics such as the form of the external genitalia as well as the organization of various neural systems and is determined by whether the sperm contributes an X or a Y sex chromosome when it fertilizes the egg. If the sperm contains an X chromosome, the resulting XX mix causes the fetus to develop as a phenotypic female. When the ovaries begin to secrete gonadotropins, the secondary sex characteristics and the brain will be feminine. If the sex chromosomes are XY, testis will develop, and the secondary sex characteristics and the brain will be masculine.

The critical gene that determines whether or not the gonads will become either ovaries or testes is located in the middle of the short arm of the Y chromosome. The gene is called the sex-determining region of Y and encodes for production of testes-determining factor (TDF). The presence of TDF causes the testes to develop. The testes in turn secrete two hormones that are responsible for the phenotypic development of the fetus as a male. If these hormones are lacking, no signals are sent to alter the intrinsic default developmental sequence, and the fetus develops as a female. Testosterone, secreted by the Leydig cells of the testes, changes the sex organs, mammary gland anlage, and nervous system into the male pattern. The second hormone is secreted by the Sertoli cells of the testes and is called Müllerian duct-inhibiting hormone (MIS). MIS causes the tissues that would become the oviducts, uterus, cervix, and vagina to be resorbed.

Although conducted before the discovery of MIS, an early experiment by Phoenix, Goy, Gerall, and Young serves to distinguish the roles of these two hormones and demonstrates the importance of testosterone for masculization of adult behavior. Fetuses of both sexes are exposed to high estrogen levels from the mother's circulation. Thus the primary secretion of the fetal ovaries is reinforced by estrogen from the mother. Phoenix and colleagues wondered what would happen if female fetuses were exposed to higher than normal levels of testosterone. To answer this question, they injected large amounts of testosterone into pregnant guinea pigs. The external genitalia were unequivocally male, but the internal genitalia were female. These animals were now pseudohermaphroditic. The explanation of this phenomenon is that the external genitalia were shaped as male by the influence of the testosterone; however, the oviducts, uterus, cervix, and vagina existed because these guinea pigs were not exposed to the second testicular hormone, MIS, so development of the internal genitalia proceeded according to the default female plan.

The second observation was more important. In normal adult female guinea pigs, administration of estrogen and progesterone produces strong lordosis when the female is mounted by the male. Lordosis is a gender-specific behavior activated in the adult female by the presence of estrogens in the circulation. Phoenix and colleagues found that the female guinea pigs exposed to testosterone in utero demonstrated little lordotic behavior when injected with estrogen and progesterone as adults. However, although they had functioning ovaries, they displayed as much mounting behavior as male litter mates when injected with testosterone. Mounting behavior is often used as an experimental index of the male behavior pattern and is seldom seen in normal adult females, even with testosterone injections. Prenatal exposure to testosterone may have not only produced masculine external genitalia but may also have changed parts of the circuitry of the brain to the masculine pattern.

There are relatively short critical periods in the development of the animal when manipulation of levels of sex steroids makes a difference in development of adult patterns of sexual behavior. Rats have a 21-day gestation period. The testes appear on the 13th day of embryonic life and secrete androgens until the 10th day after birth. Androgen secretion then virtually ceases until puberty. Castration at the day of birth causes male rats to display female sexual behavior as adults when injected with estrogen and progesterone and mounted by normal males. Male rat pups castrated after postnatal day 10 will not display lordosis as adults. This suggests that there is a short critical period when the brain is influenced by testosterone to develop circuitry for male sexual behavior.

Furthermore, the anterior pituitary of both males and females secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH). As noted previously, release of hormones from the anterior pituitary is under control of the hypothalamus. In males, LH and FSH are released at a steady rate, but in females, the release of these hormones is cyclical, and their levels are related to the cyclical activation of the reproductive organs. If male rats are castrated shortly after birth, cyclical release of LH and FSH will occur. If ovaries are implanted into adult genetic males that were castrated within 1 day of birth, these ovaries can cyclically ovulate, and the host male rats demonstrate behavior normally shown by females in estrus.

Exposure to higher-than-normal levels of androgens at

critical periods clearly can produce male behavior in genetic females, and lack of exposure to these hormones can feminize genetic males. Thus females exposed to high levels of testosterone during the critical developmental periods will exhibit mounting behavior at a rate similar to that of genetic males, and males lacking testosterone during the critical period will fail to exhibit mounting behavior, but will exhibit lordosis when exposed as adults to estrogen. A correlated observation to the results of these experimental manipulations is that in normal males and females, exposure to homotypic hormones (i.e., hormones appropriate to the sex of the animal) can trigger sex-specific behaviors (e.g., lordosis on exposure of a normal female to estrogen and progesterone). These observations suggest that the brain (1) must be responsive to sex steroids, and (2) there should be differences in organization of at least some parts of the brain between males and females.

For the central nervous system to respond to gonadal hormones, receptors for androgens, estrogen, and progesterone must exist in neural tissue. Such receptors are located in neurons found in several regions of the central nervous system of the rat and monkey. These areas include not only the hypothalamus, but also the frontal and cingulate cortex, amygdala, hippocampus, midbrain, and spinal cord. Unlike receptors for neurotransmitters, receptors for sex steroids are typically found in the cell nucleus, not in the cell-limiting membrane. Therefore, rather than changing plasma membrane properties, gonadal hormones influence DNA and the transcription of genes. This action permits these hormones potentially to exert influence over many functions of the cell.

The presence of receptors for the different gonadal hormones in the brain differs between the sexes. For example, it was noted previously that in females LH is released in relationship to the cyclical activation of the reproductive organs, whereas in males LH release is continuous at a steady level. Release of LH is regulated by neurosecretory cells of the anterior pituitary that secrete LH-releasing hormone (LHRH). The LHRH neurosecretory cells do not have sex-steroid receptors. These cells, however, receive neural input from neurons in the preoptic area of the hypothalamus. These preoptic neurons do have receptors for estrogen. Thus in normal females, as the ovarian follicles grow, the secreted estrogen stimulates neurons in the preoptic hypothalamus, which in turn stimulate LHRH neurosecretory cells to produce LH. In the brains of genetic females that have been exposed to high levels of androgens either prenatally or immediately postnatally, the preoptic cells do not express estrogen receptors and do not respond to estrogen activation. Therefore, the male pattern of LH secretion ensues.

The structure of the brain differs between males and females. The most obvious example is the sexually dimorphic nucleus located in the preoptic area of the hypothalamus. This nucleus is much larger in males. Unfortunately, its function is not known. Raisman and Field observed differences in organization of input to the preoptic area of the hypothalamus.

In addition to their influence on reproductive behaviors, the gonadal hormones also may have organizing and triggering effects on other types of behavior. For example, aggression between males is positively related to testosterone levels, whether the males are competing for a female. These effects may be related to neural events taking place in the medial and preoptic hypothalamus. Aggressive play is much more prevalent in male animals, and the incidence of this form of play is sharply reduced in male rats if they are castrated before postnatal day 6, but not if they are castrated later in life. Conversely, female rats given large doses of testosterone within the first 6 days of life exhibit as much aggressive play as males when this activity develops several weeks later. Similar findings have been reported for monkeys, but the manipulations must be made prenatally.

In summary, gonadal hormones have the capability of organizing behaviors if administered during certain critical periods of development of the organism. Presumably, this organization is due to the influence of these hormones on the developing brain circuitry, but the exact causal sequence between hormonal release and final brain circuit is not known. The exact timing of the critical periods when gonadal hormones can permanently influence behavior varies according to species, but critical periods occur either late during gestation or immediately after birth. The behaviors organized are those related to sexual activity but also include other behavioral patterns, particularly those reflecting aggression. Exposure to gonadal hormones also can activate behaviors such as mounting or lordosis in adults if appropriate sensory events, such as a receptive female in the case of male mounting behavior, are present. Gonadal hormones also influence the actual morphology of the sexual organs and secondary sex characteristics. Alterations in external sex characteristics might also influence behavioral expression, particularly in humans for whom sex roles are heavily influenced by gender assignment based on external appearance and consequent social learning.

GOLDMAN EQUATION

In 1943, the chemist David Goldman studied salt flow through artificial membranes and described his results with an equation now known as the Goldman equation. His

work remains important in psychology because the difference between sadness and happiness, good mood and bad mood, and even sanity and mental illness depends on the flow of charged salts (ions) through the protein channels puncturing neural membranes. For example, cocaine opens some Ca^{+2} channels; a mutation in some K^+ channels is thought to be associated with Schizophrenia; and general anesthetics keep GABA-sensitive Cl^- channels open longer.

Much of any cell's function is controlled by changes in the voltage across its ultrathin insulating wall. For a typical voltage of 100 mV across the 10 nm-thick membrane, the electric field strength is about 10 million V/m (about ten million volts across a doorway!). It should not be surprising, then, that small voltage changes can alter cell function by contorting the charged channel proteins. This is particularly true of voltage-controlled channels. Similarly, changes in the local electric field within stretch-sensitive channels due to slight membrane stretch alters ion flow through them, making them useful in cell volume regulation and detection of atomic movements throughout the body (in the ear, skin, muscle spindles, joints, etc.). For ligand-mediated channels, ion flow is altered by changes in the local electric field caused by bound hormones, drugs, or neurotransmitters. Because all of these channels are crucial in the electrical and chemical communication within and between cells, we clearly need to understand how channels open and close, how membrane voltages determine ion flow, and how ion flow determines membrane voltage.

Equilibrium

If an ion x (say, Na^+, K^+, or Cl^-) passes through a particular type of channel, the electrochemical potential energy difference (μ_x) driving the ion through the channel is given by $\mu_x = z_x V + E_{10} \log_{10} (x_o/x_i)$, where V is the voltage across the membrane, z_x is the ion's charge, and x_o and x_i are its concentrations, or activities, inside and outside the cell. $E_{10} = (2.303\text{k}T/q)$, where q is the proton charge in Coulomb, k is the Boltzmann constant, and T is absolute temperature in degrees Kelvin (Adamson, 1973; Hille, 1992). At 38°C, $E_{10} = 60$ mV. Diffusion of ion x is equal in both directions (equilibrium occurs) when $\mu_x = 0$ for $V = E_x = (E_{10}/z)\log_{10} (x_o/x_i)$, where E_i is the equilibrium voltage for x.

Nonequilibrium

While important, this last Nernst equation has limited practical application because ions are not often at equilibrium (except after death). Most often $V \neq E_x$, and there is a net ion flow or current through channels, approximated by the modified Goldman-Hodgkin-Katz (GHK) current equation

$$I_x = (n_x g_x p_o)[(z^2_x q/E_{10})V(x_i - x_o 10^{-z_x V/E_{10}})/(1 - 10^{-z_x V/E_{10}})]$$
$$= P_x \text{GHK}_x$$

where n_x is the number of channels in the membrane, with a probability of opening of p_o and a single-channel conductance of g_x. The product $P_x = (n_x g_x p_o)$ is the membrane's permeability to ion x.

Graphical Interpretation

While the GHK equation appears daunting, it is most easily appreciated in its graphical form, in which it describes the current-versus-voltage (IV) curve for the ion/channel combination. As shown in Figure 1A, the shape of the IV curve is defined by the complex term within square brackets (GHK_x) and varies with the concentration ratio (x_o/x_i), and the magnitude of the current is scaled by the permeability P_x (Figure 1B). The IV curve passes through the ordinate ($I_x = 0$) at equilibrium, where $V = E_x$. As for P_x, the channel density n_x is determined genetically, is often up- and down-regulated during cell function, and may also be altered with drugs; and the channel conductance g_x may change with drugs or a genetic mutation (e.g., cystic fibrosis or Schizophrenia). For voltage-controlled channels, p_o often follows a simple Boltzmann function $p_o = 1/[1 + 10^{(V - V_{1/2})/V_{11}}]$, where $V_{1/2}$ is the voltage at which $p_o = 1/2$, and V_{11} is the voltage change from $V_{1/2}$ required to increase p_o from 1/2 to 10/11, or decrease it from 1/2 to 1/11 in the other direction. Because p_o is a strong function of V for voltage-controlled channels, their IV curve can take on complex shapes, often either N-shaped (Figure 1C) or L-shaped (Figure 1D). For stretch-sensitive channels, p_o is often described by a Boltzmann function, with $p_o = 1/[1 + 10^{(d - d_{1/2})/d_{11}}]$, where d is the membrane deformation, $d_{1/2}$ is the membrane deformation at which $p_o = 1/2$, and d_{11} is the displacement away from $d_{1/2}$ required to increase the opening probability from 1/2 to 10/11, or from 1/2 to 1/11 if the displacement is in the other direction. For ligand-mediated channels the opening probability is often a saturating function of the concentration (C) of the molecular ligand, and if n (the Hill coefficient) ligand molecules must bind to the channel receptor to open the channel, the opening probability is given by $p_o = [C/(C + K_{sat})]^n$, where K_{sat} is a binding parameter that determines the onset of saturation, and n is the Hill coefficient.

All Ions Combined

Of course, the parameters are different for different channel types, and different values of z_x, x_o, and x_i apply to each ion x. Nevertheless, if all ions flowing through a membrane share the same V (assuming no local charge screening), and we ignore ionic currents through membrane pumps and carrier molecules, then the total current is the sum of all channel currents, and the total IV curve is the vertical sum of each separate IV curve. Assuming only one type of fixed channel for each major ion (Na^+, K^+, and Cl^-), with permeabilities P_{Na}, P_K, and P_{Cl}, the total current would be $I_{tot} =$

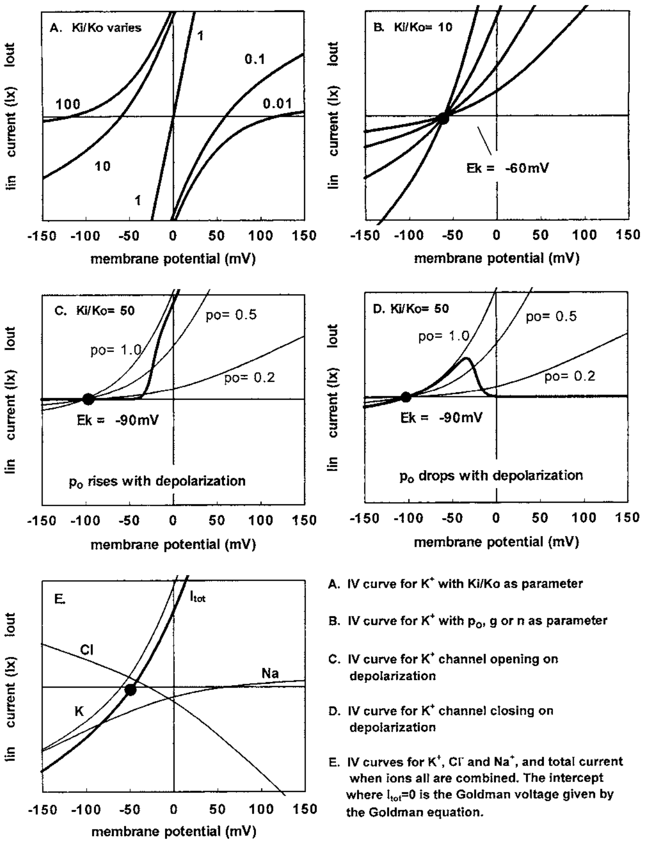

Figure 1. Membrane potentials.

$P_{Na}GHK_{Na} + P_K GHK_{Na} + P_{Cl}GHK_{Cl}$ (Figure 1E), and the net current is zero at a particular voltage, V_m, which is not necessarily equal to E_{Na}, E_K, or E_{Cl}. This resting membrane voltage is important because it is the only voltage that is stable: When $I_{tot} = 0$, the membrane is neither charging nor discharging, and the voltage remains constant as long as the concentrations remain fixed. It can be shown that $I_{tot} = 0$ for a value of V_m given by the Goldman equation $V_m = E_{10}\log_{10}[(P_{Na}Na^+_i + P_K K^+_i + P_{Cl}Cl^-_o)/(P_{Na}Na^+_o + P_K K^+_o + P_{Cl}Cl^-_i)]$ Clearly the resting membrane voltage changes with the concentration ratios (as in sensory cells, like Na^+ detection on the tongue), or permeabilities (as in sensory cells, in neurotransmission, and during drug action).

Problems with the Goldman Equation

While useful as a first approximation, the Goldman equation is not applicable when cells or their environments are asymmetrical, because different permeabilities and ion concentrations apply around the cell's perimeter. The equation is also inappropriate when significant current flows through membrane pumps or carriers, as in salt transport epithelia. Nevertheless, in symmetric cells dominated by channel currents, the Goldman equation estimates the membrane voltage. If ion x dominates because of its large concentration or high permeability, the Goldman equation simplifies to the Nernst equation, and V_m tends to E_x. Finally, if an ion is not being pumped through a membrane, it ultimately distributes passively across the membrane according to its charge and the membrane voltage, and cancels itself out of the Goldman equation. It is common, then, for such passive ions to be excluded from the equation at the outset. This is problematic because the passive redistribution of passive ions takes time, and passive ions can still modify rapid voltage changes such as action potentials or postsynaptic potentials.

GRIEF

Grief is usually defined as a person's constellation of responses to loss and bereavement. As a universal human phenomenon, it has biological, cultural, and unique individual components.

Grief's biological aspects can be seen as having roots in the behaviors of animals. Greylag geese were observed by ethologist Konrad Lorenz (1952) as having a pattern of restless searching for a lost mate. Bereaved primates such as rhesus monkeys exhibit patterns of depressed behavioral activity, lowered bodily temperature, and whimpering. Elephants have been reported to bury dead animals (including humans). Thus, it can be said that grief is not limited to the realm of the human but is deeply rooted in animal experience.

Cultural determinants of grief are seen in the great range of grief reactions throughout history. For example, today's Western cultural norms of grieving are very different from earlier practices largely because witnessing death is a relatively rare experience. In the Middle Ages, an individual might have known, every year, about 100 people who died of childhood illnesses, of plagues, or of a variety of other causes that are uncommon today. Rituals such as the *nuntius mortis* (asking a close friend to play the role of letting you know when you looked like you might be getting mortally ill so that you could prepare for a good death) were commonplace.

Individual aspects of grief are the result of many factors in addition to the cultural and biological. These include the personality and coping history of each griever, his or her relationship with the deceased, and the circumstances surrounding the loss.

John Bowlby (1980) had demonstrated the importance of affectional bonds or attachments. We form such bonds through simple close contact with another. Many of our needs, especially needs for safety and security, are met through our attachments to intimate others. As a result, the death of someone to whom we have been attached is a painful experience.

The experience of losing someone to whom we have been

attached occurs on at least four levels, according to thanatologist J. William Worden (2001). Thus, grief is normally seen in the many ways that reflect these levels of experiencing. Knowing that these are normal reactions can sometimes bring a measure of reassurance to the grieving person.

1. Normal *feelings* include sadness (the most common feeling), shock, numbness, yearning, loneliness, guilt, anxiety, helplessness, fatigue, and anger.
2. Normal *cognitions* include confusion, difficulty concentrating, disbelief, preoccupation, and hallucinations (thinking one has just seen or heard the deceased).
3. Normal *behaviors* include crying, sleep disturbance, eating disturbance, restlessness, and searching and calling out to or dreaming of the deceased.
4. Normal *physical sensations* include oversensitivity to noise, a lump in the throat, tightness in the chest, shortness of breath, dry mouth, lack of energy, and muscle weakness.

Others, notably Corr, Nabe, and Corr (2000), have included two additional levels.

5. *Social* disturbances include withdrawal, problems in relationships, and problems working in groups (e.g., at work).
6. *Spiritual* disturbances include anger with God, a search for meaning, and a sense that previous ways of making sense of life are now inadequate.

It is important, according to research by Thomas Attig (1996) and others, to recognize that grieving is a process of coping. It is a process that demands energy and presents the grieving person with tasks, choices, and opportunity for growth.

The grieving process has been characterized by several theorists as occurring in phases or stages. Perhaps the best-known phase model has been that of Colin Murray Parkes (1987). Drawing on the work of Bowlby, Parkes (1987) described four phases:

1. Shock and numbness (an initial reaction of feeling dazed)
2. Yearning and searching (protesting the reality of the loss)
3. Disorganization and despair (questioning one's sense of self and disorganized cognitive schemas)
4. Reorganization (making sense of one's life, including integrating the loss into one's scheme of things)

Phase models have considerable face validity because they seem to describe experiences common to many people. However, their emphasis on sequence may not best describe the process of grieving. It may be more accurate to describe the phases as overlapping and often repeating events following a loss.

A different approach to grieving has emphasized the tasks involved in the process. Worden (2001) has offered the best-known of the task models. In its stressing the importance of tasks in the grieving process, this approach can be therapeutic. The active accomplishment of tasks frames grieving as a process in which the individual exercises his or her self-determination of the outcome. The tasks of mourning are

- Accepting the reality of the loss—the facts of the loss as well as the meaning of the loss
- Experiencing the pain;
- Adjusting to an environment in which the deceased is missing—learning new skills, taking on the roles of the deceased, and otherwise adapting
- Emotionally relocating the deceased and moving on with life—reinvesting one's emotional energy without forgetting the deceased

Grieving can often be an active process with opportunities for growth and self-definition. Catherine Sanders (1998) has contributed the concept of a "decision point" that most people seem to reach after the early (perhaps more biologically influenced) aspects of grieving. She points out that a grieving person makes a decision, sometimes unconsciously, to survive and go on with a new life or to remain in a state of bereavement.

A widely accepted approach to grieving and grief therapy focuses on the individual's reconstruction of meaning. Robert Neimeyer (2000), the editor of *Death Studies,* has articulated this idiographic model that emphasizes each individual's unique experience of grieving. The revision of one's life story is the central process in grieving, and grief therapy is an opportunity for grieving persons to tell their life stories in ways that will help them make sense of loss and of life.

Human life can be seen as a process of telling one's story. Through telling and revising our stories, people develop a sense of meaning, purpose, and self. Losses and deaths disrupt our stories. They can threaten assumptions that have given meaning and order to our lives. Significant losses can initiate a search for meaning. Recent studies indicate that at least 70–85% of bereaved persons engage in a search for meaning in their lives. Research by Davis, Nolen-Hoeksema, and Larson (1998) has found that this search usually centers on two kinds of questions. Early questions try to make sense of the loss: "Why did this happen? What is the meaning of this loss (death)?" Later questions try to find benefits from the loss: "What can I learn from this experience?" or "What is the meaning of this experience in my life?" Neimeyer (2000) has said that such new meanings become part of the grieving person's broad scheme of things. Thus, for most people bereavement can be a time for look-

ing at such existential questions as "What is the purpose of my life? Who am I?"

Grieving can ultimately be a time of learning about oneself. We learn about ourselves by observing our own behaviors following a loss, by listening to our own answers to existential questions, and by revising our life stories following the urgent experience of bereavement. A growth outcome of grieving can be increased self-perception and self-definition.

GROSS MOTOR SKILL LEARNING

The acquisition of motor skill, sometimes referred to as *motor learning,* has been the object of a great deal of experimental work. By far the most popular apparatus for such study has been the pursuit rotor or rotary pursuit test.

The most important variable affecting performance during the acquisition of skill is *distribution of practice.* Typically, performance is very much better with spaced practice than with massed practice. Special procedures employed along with distribution of practice reveal certain other important phenomena. For example, a rest of 10 minutes or more following a series of massed-practice trials produces an increase in performance called *reminiscence.* This spontaneous improvement means that the reduced performance under massed practice is an effect on performance exclusively; massed-practice subjects have learned just as much as distributed-practice subjects.

Sometimes this last fact is partially obscured by the subjects' need to warm up after the rest following massed practice. The theory that the effects of distribution are on performance rather than on learning is further supported by the data obtained following a test for reminiscence. If the subjects are returned to a massed-practice schedule of trials, their performance decreases. Somewhat surprising, this decrease typically continues until the learning curve has returned approximately to the level where it would have been if no rest period had been introduced; then performance begins to increase. If subjects switch to distributed practice following the rest, their performance shows no trace of the previous experience on massed practice after the necessary warmup.

Greg A. Kimble

GROUP COHESIVENESS

Group cohesiveness has been defined in many ways. Leon Festinger defined the concept in terms of forces that lead an individual to remain in or leave a given group. One way to understand group cohesiveness rests on the idea of "task." Implicitly or explicitly, every group has a task or tasks it must accomplish. Many schemes have been presented for categorizing group tasks. Some approaches have emphasized the unconscious motives harbored by group members. Others have specified aspects of communication among group members. Still others have focused on the content of observed aspects of the work of the group. The extent to which members of a group identify with and work toward a common task is a measure of group cohesiveness.

What influences group cohesiveness? Although Rabbie and colleagues have suggested that competition between groups has no more effect on ingroup cohesion than does intergroup cooperation, the majority of writers over the years have agreed that hostility toward an outside person or persons serves to strengthen cohesiveness within a group.

Bion suggested that group tasks often derive from members' unconscious and primitive needs and expectations. He classified these activities as *dependence, fight–flight,* and *pairing.* These activities reflect assumptions shared by all

in the group. The task or purpose of the *dependent group* is to be sustained by a leader. In the *fight–flight group* the purpose is simply to defend against some threat, either by fighting someone or something or by running away. In the *pairing group* the members act as if their purpose is union and some new entity will derive from that unity. Bion believed that it was necessary to attend to both work and basic aspects of group activity to fully comprehend a given group and such group considerations as cohesiveness.

To explain how individuals in a group come together to behave toward some common end, Thomas French developed the concept of "focal conflict." Similar ideas have been postulated by other writers as well. In general, such notions refer to a tendency for groups to attend to topics that have relevance, often by reducing anxiety for all members. Many specialties have concerned themselves with group phenomena. Personality and psychotherapy theorists, social and organizational psychologists, anthropologists, and educational specialists are but a number of professions interested in this topic. Diverse methods and emphases have influenced conclusions. An integration of findings about group cohesiveness has not yet been achieved.

Stanley Berent
University of Michigan

GROUP COUNSELING

Group counseling is typically conducted with a small number of people, usually seven to ten, depending upon the ages of the group members. The individuals in the group provide the subject matter for discussion by sharing their personal thoughts, feelings, and behavior. Group members are expected to be involved in the process by reacting to each other through feedback, support, and problem solving.

The leader usually has had special training in group counseling techniques and strives to create an atmosphere of trust, openness, responsibility, and interdependency. The leader typically models appropriate behavior and guides group members through the processes of understanding, caring, and conflict management.

Differences between group counseling and group psychotherapy center on the composition of group membership, the degree of personality change expected, and the nature of the group leader's training. Methods, procedures, and theories used in counseling and therapy groups are often quite similar.

Members of a counseling group can come from virtually any walk of life and typically fall within the normal ranges of adjustment and ability to cope with life situations. They join counseling groups to gain deeper personal insights or to develop their personal potentials. Psychotherapy group members bring more severe personality problems to the group and may be mildly to chronically neurotic, with limited ability to deal with life problems. They usually require more intensive personal work in restructuring basic personality patterns.

Both counseling and therapy group leaders require special training in the conduct of groups. Counselors typically focus their training on normal life-span development. Psychotherapists usually spend more training time with abnormal populations and in the study of psychopathology.

Group counseling owes its historical roots to the influence of group dynamics and the more established procedures used with group guidance and group psychotherapy. Groups are a natural phenomenon in human history. Forerunners of organized groups include various religious movements, drama, and morality plays. Some historians cite Mesmer's work as a precursor of group treatment.

Most, however, note the "class method" work of J. H. Pratt as the beginning of scientific group treatment in the United States. Pratt used a directive-teaching methodology with his tubercular patients as he instructed them in hygiene, nutrition, and rest. His original intention was to boost their morale through more effective cleanliness. It soon became clear that his patients were deriving more benefit from the supportive atmosphere of the group than from the information imparted in the lectures. The method more resembled what we think of as a psychoeducational group today (Berg, Landreth, & Fall, 1998).

Alfred Adler and J. L. Moreno began using group methods in Europe. Adler would counsel children in front of a group, with the primary purpose of instructing other professionals in individual psychology. The observation was made that the group or audience, as they asked questions and interacted, had a positive impact on the counseling.

Moreno used group techniques with the street people of Vienna. He worked with children, displaced persons, and prostitutes as he found them in their environments. Moreno introduced sociometry and psychodrama to the United States; he also coined the terms *group therapy* and *group psychotherapy.*

Others who have had great influence on group work in the United States include S. R. Slavson who introduced methods known as activity group therapy, initially developed with socially maladjusted children. Rudolph Dreikurs applied Adlerian principles in his work with family groups and children in Chicago. Carl Rogers and his person-centered or phenomenological approach helped further popularize group work.

Owing to influences of group psychotherapy and group dynamics, many early writers used the terms *guidance, counseling,* and *psychotherapy* interchangeably. Continuing clarification of terms and procedures along with the professionalization of school counselors and counselors in public agencies and private practice has added acceptability and credibility to group counseling.

Other influences in the acceptance of group counseling as a viable treatment include the Human Potential Movement and professional counselor organizations such as the American Counseling Association (ACA) and the American Psychological Association. Each of these major organizations has ethics codes that specifically address the area of group work.

In 1973, under the leadership of George Gazda, the Association for Specialists in Group Work was officially formed as a division of the American Personnel and Guidance Association (APGA) now the (ACA). The ACA was and is very active in the promotion of ethical guidelines for leaders and professional standards for the training of group leaders.

Yalom (1995) addressed what he termed therapeutic factors that operate in every type of counseling or therapy group. They include (1) the *imparting of information*—Included is didactic instruction, advice, suggestions, or direct guidance about life problems; (2) the *instillation of hope*—High expectations for success, hope, and faith in the treatment model have been related to positive outcomes in groups; (3) *universality*—Participation often teaches people that they are not alone or isolated with the "uniqueness" of their problems, frequently producing a sense of relief; (4) *altruism*—Group members help one another by offering support, suggestions, reassurance, and insights; (5) the *corrective recapitulation of the primary family group*—Groups resemble families in several significant ways. Many group members have had unsatisfactory experiences in their original families; the group offers an opportunity to work through and restructure important family relationships in a more encouraging environment; (6) the *development of socializing techniques*—Social learning takes place in all groups. The development of basic social or interpersonal skills is a product of the group counseling process that is encouraged by member-to-member feedback; (7) *imitative behavior*—A group member often observes the work of another member with similar problems. Through vicarious therapy the group member can incorporate or try out new behaviors; (8) *interpersonal learning*—The group is a social microcosm providing the necessary therapeutic factors to allow corrective emotional experiences. Group members, through validation and self-observation, become aware of their interpersonal behavior. The group, through feedback and encouragement, helps the member see maladaptive social and interpersonal behavior and provides the primary supportive environment for change; (9) *group cohesiveness*—It is defined as the attractiveness a group has for its members, a "we-ness," "groupness," or "togetherness." Cohesiveness in a group is analogous to connectedness or relationship between individuals. Acceptance and support demonstrated by the group can be a potent healing force; and (10) *catharsis*—The group provides members with a safe place to vent their feelings rather than holding them inside. The process encourages learning how to express feelings in general and to express both negative and positive feelings.

While these therapeutic factors are cited as advantages for the use of groups as a treatment method, there are also several risks and limitations. Corey and Corey (2002) caution that groups are not "cure-alls" and that not all people are suited for groups. Some potential members may be too suspicious, hostile, or fragile to gain benefits from a group experience. Additionally, there is often a subtle pressure to conform to group norms.

When a group member accepts the process of the group, there is the possibility of some psychological hazard. As members open up, they may become vulnerable, particularly with the significant people in their lives.

Also, absolute confidentiality is difficult to ensure: Some members may talk about what they have heard outside the group. Any treatment system as potent as a group can cause major life disruptions. Changes can occur in lifestyle and values, and in loss of security. Potential group members should be aware of these risks and limitations.

While it is doubtful that many group leaders practice from a pure theoretical position, preferring an eclectic approach, theoretical positions with the widest currency include the *person-centered model,* developed by Carl Rogers and his proponents. It is based on the assumption that human beings have an innate ability to reach their full potential. This includes the potential to solve their own problems, given a free and permissive atmosphere. Frederick S. Perls and his followers developed the *Gestalt therapy model.* Group experience focuses upon an intensive here-and-now orientation. The experiencing of the present moment provides insight into personal behavior and creates the basis upon which new decisions for behavior change can be made. Group members are taught to take personal responsibility for all of their feelings and behavior. The *Rational-Emotive Behavior Therapy model* developed by Albert Ellis uses an educational rather than a medical or psychodynamic system. Direct behavioral actions taken upon one's belief in irrational ideas that result from verbal self-indoctrination form the bases for behavior change. The goal of therapy is to assist group members in internalizing a more rational philosophy of life and thus to behave and live life more fully.

Other theoretical approaches that have gained some measure of acceptance, but that may be limited to certain distinct settings, include the psychoanalytic model, transactional analysis, cognitive therapy models, the development approach, and Adlerian lifestyle approaches.

GROWTH HORMONE ([GH] SOMATOTROPIN)

The human anterior pituitary gland contains 5–10mg growth hormone (GH), which is synthesized and stored in cells referred to as *somatotropes,* which are located in the lateral wings of the gland. The human GH gene is on chromosome 17 and its mRNA transcript possesses 5 exons separated by 4 introns. The peptide contains 191 amino acids and has a plasma half-life of 20 minutes (Dinan, 1998). GH plays an important role in the regulation of growth and trophic metabolic processes. The peripheral physiology of GH and its salutary effects in models of peripheral nerve injury (Scheepens et al., 2001) is not the focus of the current summary; the focus is how GH function may inform us about central nervous system (CNS) function in psychiatric disorders (Coplan et al., 1995).

The release of GH by the pituitary gland is regulated by many of the monoamine and neuropeptide systems, also involved in mood and anxiety regulation, acting through the hypothalamus. The release of GH, by either a provocative stimulus or a spontaneous release as part of a physiological process (e.g., sleep) has therefore been viewed as a potential window into CNS trophic function. The neuroscientific challenge remains to wholly integrate frontolimbic dysfunction, which current technology are increasingly well equipped to detect, with previously documented hypothalamic-pituitary dysfunction, which, to date, is most readily apparent with psychoneuroendocrine evaluation.

Regulation of GH Secretion

The regulation of the hypothalamic-pituitary-somatomedin (HPS) axis, responsible for GH release, occurs primarily through two main limbs—stimulation through the hypothalamic peptide growth hormone releasing-factor (GRF) and inhibition through the 14 amino-acid peptide, somatostatin (SOM). Numerous factors impact upon these two limbs, and in fact, the degree to which neurotransmitter systems impact upon either limb may vary according to interspecies differences (see Uhde, Tancer, & Rubinow, 1992). It appears that clonidine, a widely studied α_2 adrenoceptor agonist, may produce its GH secretory effect in healthy control humans either through α_2 mediated stimulation of GRF or α_2 mediated inhibition of somatostatin release. Growth hormone secretion is inhibited by high plasma GH levels, as well as somatomedin-C, which is released by the liver in response to circulating GH. Other neurotransmitter systems that impact on the regulation of GH response to clonidine include the cholinergic, dopaminergic, GABAergic, the Hypothalamic-hypopituitary-adrenal (HPA) axis (specifically corticotropin-releasing factor [CRF]) and serotonergic systems (for review, see Dinan, 1998). Age, obesity, alcoholism, phase of menstrual cycle, and postmenopausal status may also influence stimulated GH response. Less clearcut factors influencing GH response to GH secretagogues include heavy smoking, which may increase GH secretion; lifetime exposure to tricyclic antidepressants and recent exposure to benzodiazepines.

Possible Mechanisms for Blunted GH Secretion to GH Secretagogues in Anxiety and Mood Disorders

Blunted GH responses to GH secretagogues, such as clonidine, desipramine, the insulin tolerance test, and others, were thought to detect down-regulation of postsynaptic alpha-2 receptors following excessive central noradrenaline (NA) activity in major depressive disorder (Coplan et al., 1995; Siever et al., 1982). That GH responses are blunted in response to both clonidine and growth hormone releasing factor (GRF) in Panic Disorder (PD) refuted the view that reduced GH response to clonidine simply reflects a specific alpha-2 abnormality. Uhde, Tancer, and Rubinow (1992) have reviewed the possible site(s) where blunting of GH may occur. These include (1) reduced availability of pituitary GH stores secondary to reduced synthesis or excessive secretion (this option seems unlikely as GH responses to the dopamine agonist, apomorphine, are exaggerated in PD); (2) overall hypersecretion of GH with secondary inhibition of GH secretion to secretory stimuli; (3) an abnormally enhanced negative feedback system, that is, increased pituitary sensitivity to the inhibitory effects of GH or somatomedin-C; (4) subsensitivity of the pituitary to the secretory effect of GRF or reduced GRF; (5) failure of clonidine to reduce the inhibitory effect of somatostatin neurons on the pituitary; and (6) abnormal function of a host of other factors previously enumerated. It should be noted that blunted GH secretion is not only observed in PD and depression but also in Generalized Anxiety Disorder (GAD) and possibly Social Phobia. GH responses to GRF and clonidine in childhood depression also tend to be blunted. However, the abnormality is not observed in Schizophrenia or Obsessive-Compulsive Disorder.

Investigators have argued that reduced GH responses to chemical or physiological stimuli in Anxiety and Mood Disorders may represent a trait marker of vulnerability to Mood and Anxiety Disorders. Coplan, Pine, Papp, and Gorman (1997) have presented evidence in both patients with PD as well as in unpredictably reared nonhuman primates that the GH response to the GH secretagogue,

clonidine, varies inversely with the degree of HPA axis activation. More recent work with nonhuman primates has provided even stronger evidence of a negative correlation between CRF and GH secretion (Coplan et al., 2000a). Examining juvenile neurochemical levels of CSF, CRF, 5 hydroxy-indole-acetic acid (serotonon metabolite) (5-HIAA), HVA, SOM, 3-methoxy-4-hydroxy phenylglycol (noradrenaline metabolite) (MHPG), and CSF cortisol revealed that only levels of CSF and CRF were significantly correlated with GH response to clonidine. An inverse relationship involving the CRF and HPA axis and GH may be an enduring, trait-like feature observed in association with both stressful early rearing and Mood and Anxiety Disorders.

Nocturnal Growth Hormone Secretion

Sleep onset represents a highly evolved, dynamic biological process, involving the reduction and ultimate cessation of noradrenergic and serotonergic neuronal activity, the onset of cholinergic "bursts" of firing from pontine nuclei and the increased secretion of GH primarily through muscarinic inhibition of SOM, the GH secretagogue suppressant. During the early phases of sleep, increases of spontaneous GH secretion have been associated with slow wave (delta) sleep, the former subsiding several hours following sleep onset. The elevations of CRF and cortisol increases that are frequently evident in Mood Disorders are inhibitory towards GH secretion and imply a ratio increase of CRF to GRF in adult depression (Holsboer, 1994).

Thus, adults with acute Major Depressive Disorder (MDD) quite consistently *hyposecrete* GH around the time of sleep onset. Studies followed depressed subjects into a drug-free recovery phase and found persistence of sleep-related GH hyposecretion, suggesting that this may be a trait marker for MDD. Investigators have proposed that secretion of growth hormone at night may be phase advanced in depression such that secretion occurs just prior to sleep onset instead of during the first few hours of sleep. Of interest, one group of investigators has reported that the phase-advanced GH peak is phase-delayed into the normal range after recovery from the depressive state, in contrast to the persistent, trait-like nature of the blunted nocturnal GH secretion in adult depression.

Puig-Antich (1987) hypothesized that a serotonin deficit state with cholinergic dominance could lead to sleep-related GH hypersecretion in prepubertal depressives. Coplan and colleagues (2000) examined unperturbed serial GH measurements over a 24-hour period in depressed and normal control adolescents in light of 10 years of clinical follow-up data. A reanalysis of diagnoses demonstrated that lifetime-depressive subjects (subjects who were initially depressed and those who became depressed over the 10-year period) exhibited low levels of GH in the 100 minutes before sleep relative to lifetime depression-free subjects.

Growth Hormone and Neurogenesis

GH also appears to play an important role in the newly described phenomenon termed *neurogenesis,* or new neuronal division in the CNS. A major mediator of the trophic effects of GH throughout the body is a mediating hormone, insulin-like growth factor-I (IGF-I), with increased gene expression of IGF-I through GH exposure (Pankov, 1999). It has been recently demonstrated that IGF-I has a clear stimulatory effect on both cell proliferation and neurogenesis in the rodent hippocampus (Anderson, Aberg, Nilsson, & Eriksson, 2002), providing indirect confirmation of GH involvement in neurotrophic processes. Because it appears a range of antidepressant and mood stabilizing interventions increase neurogenesis, the blunted GH response to clonidine observed in PD, depression, and GAD should be considered within the context of GH-sensitive IGFs as promoters of neuroprotection and neurogenesis. Studies of GH secretion hyposecretion are therefore informative as a peripheral index of central neuroprotection and also a possible site for neuroprotective deficits in Mood and Anxiety Disorders.

H

HALFWAY HOUSES

Halfway houses are locales where all activities and interactions may be viewed as having potentially healing, rehabilitative, and supportive properties and where all members may consciously or unconsciously contribute to therapy. Halfway houses typically work to prepare individuals to move from institutionalized settings to becoming able to function independently. Also, it is the goal of halfway houses to integrate or reintegrate their residents into independent living members of their communities. In some cases, the halfway house may be the first referral source or an intermediary step before a person is institutionalized. Halfway houses are commonly affiliated with churches, private organizations, hospitals, and the government and may differ greatly in the number, gender, and age of residents they serve, as well as the type of therapeutic approach they offer residents.

History

For many years, there have been organizations and individuals that have sought to help people dealing with any number of situations and conditions adjust to living and being functioning members of society. After World War II there were homes set up to help soldiers make the transitions from war to living in their respective communities. During the 1960s, with the impetus toward deinstitutionalization of the mentally ill, the advances made with psychotropic medications, and the new community mental health legislation, the number of halfway houses increased greatly. As the emphasis on transitional facilities for the mentally ill grew, there was an increased amount of attention paid to helping individuals in the criminal justice system and with substance abuse problems make the transition from institutional life to becoming acclimated to the community. Today, there are halfway houses serving a variety of populations with a variety of issues.

Types of Residents Served By Halfway Houses

The Mentally Ill

Residents are usually required to attend some type of treatment, whether it is on site or off. The staff ensures that residents take their required prescription medication regularly and properly. A great deal of treatment focus is placed on social and vocational skills. In some cases, aftercare for these clients is provided after they leave the house.

Substance Abusers

Individuals recovering from addiction are often sent to halfway houses after they have completed time in a residential treatment facility. Enrollment in a treatment program is mandatory, and no alcohol or drugs are allowed to be used by residents. The halfway house facilitates sobriety, provides support from people with similar problems, and helps residents to readjust to living in the community.

Criminal Offenders

Incarcerated individuals are often sent to halfway houses to serve out the remainder of their sentences if they have demonstrated good behavior, or they are sent to halfway houses after they are released from prison. These homes can be for either adult or youthful offenders. There is an emphasis on finding and maintaining employment. Sobriety is also usually required for these residents.

Troubled Adolescents

Children with severe behavioral problems, emotional problems, or volatile home situations are often sent to halfway houses. These children are normally residents until they can be provided with alternative stable housing or until their behavior changes. Training children in social skills is a large component of these programs. The halfway house is staffed by personnel around the clock who monitor the children's schoolwork, chores, and recreations.

The Developmentally Disabled

In halfway houses for the developmentally disabled, the staff works to help the residents function independently. Residents learn skills such as how to manage their money, cook, clean, and utilize different modes of public transportation. Some residents attain and maintain jobs while staying at the home. Many of the residents go on to

live on their own or function well with minimal help from others.

Methods

There are four basic theoretical approaches taken by halfway houses: democratization, communalism, permissiveness, and reality confrontation. *Democratization* refers to involvement of the staff and patients in the important decisions made in the running of the house. House administrators who subscribe to this approach believe that democratization may decrease resident dependence on the staff and foster independence and inventiveness in the residents. Halfway houses that follow a *communalism* model encourage staff and residents to take part in the activities of the home together. The interaction of staff and residents provides more instances to model and teach desired behaviors. Houses that follow the *permissiveness* model allow a greater expression of emotional and behavioral displays than most traditional settings before physical or behavioral restraints are used. In houses that apply the *reality confrontation* model, patients receive the same response to and consequence from their actions and behaviors that they would in the community.

Halfway house staff members employ several techniques within these modalities to aid in the adjustment of their residents to community life. Group and individual therapy, 12-step programs, social skills training, development of financial management skills, social outings, job training, and moral support are used by many house staffs to foster the independence of their residents. Many houses use some type of reward system, whether it is a token economy, gaining of privileges as skills are mastered, or acquisition of rewards and privileges with seniority as one moves through the program of the house. These tools are used in many combinations, often depending on the population of residents and the philosophical orientation of the organization, to help the residents to be able to become integrated into the community.

The ideals on which the halfway house model is built may seem quite laudable. Nonetheless, the efficacy of such programs has not yet been adequately demonstrated. There has been a wide array of studies producing various results. Several methodological issues, such as the lack of control groups in research and the lack of random assignment, have been raised in relation to studies done on halfway houses. Also, due to the various modalities of treatment and different populations served, it has been difficult to conduct research and determine effectiveness. Greater emphasis should be placed on using empirically supported methods in working with residents instead of using antiquated methods that may not be appropriate for the population.

DePaul University, Chicago

HALLUCINATIONS

Hallucinations are involuntary sensory experiences that are perceived as emanating from the external environment, in the absence of stimulation of relevant sensory receptors. Hallucinations can occur in a variety of contexts but are perhaps most striking and debilitating in the setting of Schizophrenia, where they are generally experienced as real, emotionally significant, and related to concurrent delusions, and represent a form of psychosis. Hallucinations can occur in any sensory modality or can involve multiple modalities, with auditory hallucinations being most common in Schizophrenia and other illnesses that are traditionally termed psychiatric, and visual hallucinations being most common in illnesses termed neurologic. Hallucinations can be described at multiple levels of analysis, including cognitive, neurochemical, computational, and social/psychological. This article will present a functional neuroanatomic approach to hallucinations, describing and analyzing them in terms of disorders of sensory input, subcortical (midbrain/thalamus), and higher brain regions including cortical sensory, limbic, and frontal regions. It will touch also upon treatment considerations.

Disorders of Sensory Input Associated with Hallucinations

Hallucinations produced by disorders of the peripheral sensory system appear to result from ongoing cortical sensory processing in the setting of degraded or absent sensory input. In this setting, perception may be dominated by the cortically generated expectations (top-down processing) that interact with peripheral input (bottom-up processing) in the generation of normal perception. Hallucinations of this sort are most frequently seen in the visual system, where they are termed the *Charles Bonnet Syndrome.* These are usually vivid, colorful representations of people, animals, trees, and so on that appear smaller than normal (Lilliputian) and are often engaged in activities. Notably, the individuals experiencing these hallucinations are aware that they do not represent reality, and generally they have no strong emotional reaction to them. Similar hallucinations can occur in conditions, such as stroke, that involve destruction of primary visual cortex, as this region provides input to unimodal association areas involved in the generation of complex hallucinations. When lesions are limited to one hemisphere, hallucinations may occur only in the affected contralateral visual field.

In the somatosensory system, a striking example of hallucinations caused by disordered sensory input occurs in the phantom limb syndrome, in which an amputated limb continues to be experienced as present, able to move in space, and able to feel pain or tingling. In the auditory sys-

tem, individuals with peripheral dysfunction (including deafness) can develop complex hallucinations such as music or voices, or simple hallucinations such as ringing, buzzing, or isolated tones.

Midbrain/Thalamic Disorders Associated with Hallucinations

Hallucinations similar to those produced by peripheral lesions can occur with lesions of the upper midbrain and adjacent thalamus. Originally attributed to a lesion in the midbrain peduncular region, they remain known as *peduncular* hallucinations. Like Charles Bonnet hallucinations, they are usually vivid visual hallucinations, frequently of people or animals, sometimes Lilliputian, often moving. Unlike those produced by peripheral lesions, peduncular hallucinations are generally associated with disturbances in sleep and arousal and may at times be interpreted as real.

These disturbances in sleep and arousal provide clues to the mechanism by which hallucinations are generated by midbrain and thalamic lesions. Frequency-specific oscillations in thalamocortical circuits have been associated with the temporal binding of perception, and with dreaming—a normal condition involving perception in the absence of external stimuli. During the awake state, thalamic relay nuclei faithfully transmit inputs to the cortex; during dreaming, they do not. Neurotransmitters, notably acetylcholine and serotonin, play an important role in initiating this switch in relay mode. Abnormalities of cholmergic and serotonergic transmission brought on by disease, medication, or drug use are frequently accompanied by hallucinations. Similarly, transitions between states of sleep and wakefulness are associated with hallucinations, usually in the setting of sleep disorders. These are generally multimodal, vivid, and emotionally charged. Common examples are the feeling of being about to fall into an abyss or be attacked, of being caught in a fire, or of sensing a presence in the room. Hallucinations in the settings of delirium and sedative drug withdrawal are also associated with disturbances in sleep and arousal. Such hallucinations should be distinguished from illusions, which are misinterpretations of actual sensory stimuli.

Disorders of Higher Brain Regions Associated with Hallucinations

Hallucinations, such as those that occur in migraine, epilepsy, and Schizophrenia, may also be associated with primary pathology at higher levels of the brain. In recent years, studies employing functional neuroimaging techniques have implicated a number of higher brain regions in the generation of hallucinations, corresponding to their form, content, and setting.

Cortical Sensory Activity Associated with Hallucinations

Regardless of the mechanism by which they are generated, hallucinations appear to be associated with activity in cortical sensory regions corresponding to their modality and complexity. The hallucinations previously described may be categorized as complex or formed. Noncomplex hallucinations are referred to interchangeably as simple, unformed, or crude. In the visual system, these are known as *photopsias.* Occurring most frequently with migraines, they may also be seen at the onset of partial seizures, for the first few days following an infarction of the central visual system, and with disorders of visual input. Photopsias may consist of colored or colorless glittering spots, or black and white zigzag patterns known as *fortification lines.* They often occur unilaterally, but they may fill the entire visual field. Simple hallucinations are believed to reflect activity in primary sensory or adjacent early unimodal association areas and to correspond, in form, to the area's functional specialization. For example, colored photopsias would be associated with activity in occipital subregions involved in color processing.

Complex hallucinations are associated with activity in sensory association areas, with or without involvement of primary sensory cortex. As with simple hallucinations, their form and content correspond to the location of activity. For example, in a functional neuroimaging study of an individual experiencing ongoing auditory-visual hallucinations in the setting of Schizophrenia, we detected activations in association cortices mediating higher-order visual perception, speech perception, and intermodal processing.

Limbic/Paralimbic Activity Associated with Hallucinations

The study just cited included other subjects with Schizophrenia, all of whom experienced frequent auditory hallucinations. Although each had a somewhat different pattern of sensory cortical activation, perhaps reflecting differences in the form and content of their hallucinations, group analysis revealed a significant pattern of common activations in thalamic (see earlier discussion), limbic, and paralimbic areas—regions involved in the processing of emotion, memory, and their integration with sensory information. Just as abnormal activity in sensory cortex is correlated with the form and content of hallucinations, it is likely that aberrant activity in limbic/paralimbic regions gives rise to the marked emotional significance of hallucinations in the setting of Schizophrenia.

Further evidence of a role for thalamic and limbic system dysfunction in the generation of schizophrenic symptoms is provided by postmortem, neuropsychological, electrophysiologic, and neuroimaging studies that reveal struc-

tural and functional abnormalities of thalamic and limbic regions in individuals with Schizophrenia, including hyperactivity of temporal regions, left greater than right, associated with psychosis. Additionally, activity of the limbic system is closely interconnected with that of dopamine, a neurotransmitter implicated in the generation of hallucinations and delusions in the settings of Schizophrenia, medication toxicity, and drug abuse. Recently, dysfunction in the glutamatergic excitatory transmitter system has also been implicated. Hallucinations that arise in the context of severe emotional stress may also involve abnormal limbic activity.

Temporolimbic structures also play a role in the generation of hallucinations associated with epilepsy. The onset of partial seizures can be accompanied by simple hallucinations in any modality, reflecting ictal discharges in primary sensory areas, or by complex hallucinations reflecting discharges in limbic and sensory association areas. Olfactory hallucinations can also be seen in this setting. These complex hallucinations most often involve temporolimbic regions, including hippocampus and amygdala, which have the lowest seizure thresholds of all brain structures, as well as sensory association areas. Like the hallucinations seen in Schizophrenia, these are often emotionally charged. Unlike those seen in Schizophrenia, they are more often visual than auditory and are not usually believed by the person experiencing them to represent reality. Individuals who suffer from epilepsy over prolonged periods may also develop hallucinations between seizure episodes. These may resemble more closely those seen in Schizophrenia, because they are frequently emotionally charged, accompanied by delusions, and believed to represent reality, and they are as often auditory as visual. As in Schizophrenia, they appear to be associated with temporal lobe abnormalities, left more often than right.

Frontal/Executive Activity Associated with Hallucinations

The lack of awareness that hallucinatory experience does not correspond to reality is a striking feature of Schizophrenia. In addition to temporal lobe abnormalities, numerous studies have revealed frontal dysfunction and abnormal frontotemporal connectivity associated with Schizophrenia. The frontal lobes, in concert with interconnected regions, mediate the higher, more complex aspects of cognition, termed *executive functions,* that include judgment, insight, and self-monitoring. Although relevant studies have produced mixed results, there is evidence to suggest that frontal dysfunction may contribute to the inability of individuals with Schizophrenia to identify the internal origin of their hallucinatory experience and its relation to their illness. Temporal lobe epilepsy may also be accompanied by executive as well as other forms of cognitive dysfunction, and by abnormalities of frontal activity.

Treatment of Hallucinations

For hallucinations accompanying Schizophrenia or other primary psychiatric disorders, medications that alter transmission of dopamine and related neurotransmitters (such as serotonin), termed *antipsychotics,* are the mainstay of treatment. In other settings, the first step in the treatment of hallucinations is to address the condition that underlies their existence. Where this is impossible or ineffective, antipsychotic medications may be tried. However, these tend to be less effective in conditions that do not involve limbic, striatal, or dopaminergic pathology. Fortunately, hallucinations in the setting of sensory input disorders, where antipsychotics are least effective, are often less disturbing to those experiencing them, as previously described. Such hallucinations sometimes respond to carbamazepine, a medication used to treat a variety of neuropsychiatric conditions. Where hallucinations are distressing and unresponsive to medication, psychological treatments, including cognitive-behavioral and supportive therapies, may be helpful. Future developments in the treatment of hallucinations are likely to be guided by the functional neuroanatomic approach, altering neurotransmission (via medications) or cortical activity (via techniques such as transcranial magnetic stimulation) in specific cerebral regions.

HALLUCINOGENIC DRUGS

Many drugs can produce hallucinations (e.g., LSD, scopolamine, phencyclidine, methamphetamine, bromides, alcohol withdrawal, corticosteroids), but only a few can do so without producing delirium, and those few, with LSD being the prototype, are termed *hallucinogens.* Even LSD does not usually produce true hallucinations, because the user usually remains aware that the sensory distortions are drug-induced pseudohallucinations, but this label has persisted. Hallucinogens are also called *phantastica,* psychedelics, and psychotomimetics. (Sometimes, but not herein, phencyclidine [PCP] and ketamine are called hallucinogens, but, because of their unique pharmacological properties, they are best considered in a class of their own—the dissociative anesthetics.)

The hallucinogens fall into two broad chemical classes, indoleamines (e.g., lysergic acid diethylamide, abbreviated LSD from the original German name, Lyserg-Säure-Diäthylamid; psilocybin; ibogaine; and harmaline) and phenethylamines (e.g., mescaline, methylenedioxymeth-

amphetamine [MDMA or ecstasy], 4-methyl-2,5-dimethoxyamphetamine [DOM or STP]). Some are plant constituents (mescaline from the peyote cactus, psilocybin from *Psilocybe* mushrooms), whereas others are synthetic (MDMA; LSD is semisynthetic, since the lysergic acid moiety is derived from the ergot fungus). The most potent is LSD, with a typical oral dose of 100 micrograms. Some other hallucinogens are as powerful but not as potent as LSD (mescaline is at least as powerful); that is, they are capable of exerting effects that are as profound as those of LSD, though at a much higher dose (e.g., 200–400 milligrams of mescaline). Hallucinogens are usually taken orally. Illicit LSD is often absorbed on small squares of paper printed with cartoons (in this form it is known as *blotter acid*).

Most hallucinogens, including LSD, are believed to induce their cognitive, perceptual, and mood distortions by directly activating certain subtypes of brain serotonin receptors (5-HT_{2A} and other 5-HT_2 receptors), resulting in (1) decreased tonic activity of noradrenergic neurons (via GABAergic afferents) and facilitation of the activation of noradrenergic neurons by sensory stimuli (via glutamatergic afferents) in the locus coeruleus, and (2) enhanced glutamate release throughout the neocortex (Aghajanian & Marek, 1999). There is a significant correlation between hallucinogenic potency in humans and drug agonist potency for these serotonin receptor subtypes in vitro (Glennon, 1996; Sanders-Bush, 1994). These same subtypes of serotonin receptors have been implicated in the pathogenesis of Schizophrenia. A few hallucinogens (e.g., MDMA) work primarily by releasing serotonin. Most recently, a number of genes implicated in synaptic plasticity, glutamatergic signaling, and cytoskeletal architecture have been reported to be activated upon acute LSD administration. Some of these changes are speculated to represent early sequelae in the pathways that may lead to long-term effects of LSD (Nichols & Sanders-Bush, 2002).

The psychological effects of LSD are unpredictable. They depend on the amount ingested and the user's personality, mood, expectations, and surroundings. Sensations and feelings are affected much more dramatically than somatic signs. The user may feel several different emotions (including euphoria) at once, or may switch rapidly from one emotion to another. Visual delusions, distortions, and pseudohallucinations usually occur. Colors, sounds, odors, and other sensations appear to be intensified, and pseudohallucinations of movements, forms, and events may follow. The user's perceptions of time and self are distorted, including feelings of time slowing, one's body changing shape (e.g., arms very long), and out-of-body experience. Sensations may seem to cross over (synesthesia), giving the user the feeling of hearing colors and seeing sounds. Old memories may be vividly recalled. Anxiety often occurs while using LSD and other hallucinogens, and some users experience terrifying thoughts, nightmarish feelings, despair, and fears of insanity, death, and losing control. Fatal accidents have occurred during LSD use. However, there are no documented toxic fatalities directly occurring from LSD. The somatic effects of LSD are mainly sympathetic and relatively slight. They include dilated pupils, hyperthermia, increased heart rate and blood pressure, sweating, loss of appetite, restlessness, dry mouth, dizziness, and tremors.

Users refer to LSD and other hallucinogen experiences as "trips" and to the acute adverse experiences as "bad trips," although most hallucinogen trips have both pleasant and unpleasant aspects. LSD trips are long—typically they begin to clear after 8–12 hours. Most users of hallucinogens feel that their experiences have a mystical, perception-expanding, epiphanous character. Lasting benefits, if any, of the trips have not been scientifically demonstrated. Works of authors closely associated with hallucinogens (e.g., Aldous Huxley, Timothy Leary, Alan Watts) are widely available and easy to find via the Internet.

LSD was synthesized at the Sandoz Company pharmaceutical-chemical research laboratories in Basel, Switzerland in 1938 by Albert Hofmann, who discovered its pharmacological properties in 1943, at first by accidentally ingesting a small amount and then by self-experimentation (Hofmann, 1980). Hallucinogens did not become popular until the 1960s. Their abuse declined in the 1970s but persists. LSD and MDMA are now considered to be *club drugs.* Club drugs are used by young adults at all-night dance parties such as raves or trances, dance clubs, and bars. Abuse and popularity of most club drugs are rising, whereas use of LSD has been dropping slightly since a brief increase in the mid-1990s. It may be that the dramatic increase in use of MDMA (the prototypical club drug) and ketamine displaced LSD. The 2001 Monitoring the Future Survey, funded by the National Institute on Drug Abuse, estimates that 16% of young adults (ages 19–28) have used LSD at least once, and 13% of young adults have used MDMA at least once. In 2001, among 40-year-old high school graduates, 20% reported some experience during their lifetime with LSD, but virtually no active use of LSD at this age (Johnston, O'Malley, & Bachman, 2002).

The hallucinogens are not known to produce brain damage, except MDMA, which damages brain serotonergic neurons in man and animals, and ibogaine and harmaline, both of which produce cerebellar Purkinje neuron degeneration, at least in rats. However, LSD and other hallucinogens may produce a subtle neurotoxicity not yet detected in experiments. There are two long-term disorders associated with LSD, which could possibly be caused by subtle damage to the brain-persistent psychosis and hallucinogen persisting perception disorder (HPPD; Abraham, Aldridge, & Gogia, 1996). A user of LSD may suffer a devastating psychological experience, resulting in a long-lasting psychosis. Post-LSD psychoses are unpredictable, sometimes following a single dose, but they are more common in people with prior psychopathology. Post-LSD psychoses resemble

schizoaffective disorders and are frequently accompanied by visual disturbances. The extent of this problem with the other hallucinogens is not known. However, MDMA, which does not produce the profound sensory disruptions characteristic of LSD and mescaline but instead produces primarily alterations in emotions and a feeling of empathy with others, is believed to be less likely to produce long-lasting psychoses (or HPPD). The most effective treatments for post-LSD psychoses are electroconvulsive therapy and lithium.

In the 1950s, flashbacks (spontaneous, disturbing recurrences of aspects of LSD experiences, long after the use of LSD has stopped) began to be reported, sometimes months after LSD use. The work of Henry Abraham (Abraham et al., 1996) demonstrated that this syndrome is typically persistent and stable, rather than paroxysmal, and presents primarily with visual disturbances, including geometric pseudohallucinations, false motion in the peripheral fields, halos, flashes of color, trails behind moving objects, and afterimages. The term *flashback* has been supplanted by HPPD. The visual distractions are increased by several factors, including stress, darkness, and marijuana, and are decreased by benzodiazepines.

Unfortunately, although acute, short-lived adverse reactions to hallucinogens are often fairly benign, the chronic, unremitting courses carry a poor prognosis. These long-term consequences appear to be rare, although this has not been thoroughly studied.

Hallucinogens, with the possible exception of MDMA (Cottler, Womack, Compton, & Ben-Abdallah, 2001), are not addictive. MDMA also differs from other hallucinogens in that toxic fatalities due to hyperthermia have occurred with MDMA use.

In a study conducted in the mid-1960s, when LSD was added to suspensions of human white blood cells in vitro, there was more chromosomal breakage than in the cells without LSD. This stimulated a great deal of further investigation and led to a reduction in LSD abuse, but the in vivo animal research and surveys of people who used or were given hallucinogens offered no evidence of genetic damage, birth defects, mutations, or cancer due to hallucinogens.

Use of peyote cactus in small amounts as a sacrament is legal only when used by Native American Church members. Otherwise, use of hallucinogens is prohibited; hallucinogens are categorized under the Controlled Substances Act as Schedule I drugs, which are drugs with no currently accepted medical use and/or high potential for abuse. However, the supposed insightful, epiphanous quality of hallucinogen experiences, and the vivid recall of repressed memories that occurs during use, combined with the relative lack of somatic toxicity, have led to suggested psychotherapeutic uses of hallucinogens, especially in the treatment of mental illness, including Posttraumatic Stress Disorder and substance addiction. Sandoz marketed LSD in 1949 as an adjunct in psychoanalysis. Medical use was halted in the 1960s due to the long-term adverse psychological effects previously outlined and limited evidence of therapeutic benefit. Nonetheless, psychiatric methodology has greatly improved since then, and there is renewed interest in experimentally reexamining hallucinogens (especially those other than LSD, due to LSD's reputation for producing long-lasting psychoses and HPPD) in the therapy of alcoholism and other refractory diseases. For example, although ibogaine itself may not be used therapeutically in the United States due to its neurotoxicity, studies of ibogaine analogs are continuing in animal models in the search for therapeutic agents that are not neurotoxic. Investigators are seeking to determine if it is possible to develop a therapeutic hallucinogen, novel or old, whose benefits outweigh its risks in selected patients.

HALSTEAD-REITAN BATTERY

The Halstead-Reitan Battery consists of a series of individual neuropsychological measures, that in combination permit the skilled examiner to make rather detailed inferences about the integrity of the cerebral hemispheres. Because the brain is the organ of adaptive behavior, brain dysfunction is typically observable in some behavioral aberration. The tests included in the Halstead-Reitan Battery are designed to sample behavior across every possible sphere and assess all major cognitive, sensory, expressive, and motor functions.

Ward Halstead began collecting (and discarding) tests of brain function in the 1930s at his University of Chicago laboratory. His first graduate student, Ralph Reitan, refined the battery, eliminating those tests that failed to discriminate at statistically significant levels. In addition, Reitan began a programmatic series of studies that demonstrated the utility of these tests in identifying patients with brain lesions. Recent studies have demonstrated that the predictive accuracy of the Halstead-Reitan Battery exceeds that of traditional neurological techniques (e.g., angiography and pneumoencephalography), while comparing favorably with newer techniques such as computerized axial tomography.

Many of the subtests included in the Halstead-Reitan Battery are well known and are widely used by nonneuropsychologists. These include the Wechsler Adult Intelligence Scale (WAIS) and the Minnesota Multiphasic Personality Inventory (MMPI). Other tests were developed or adapted specifically for the battery. The Category Test, for example, is regarded as one of the most sensitive measures of cerebral impairment. It consists of a series of 208 stimulus items (slides) that require a manual response from the patient. Positive or negative feedback is given in the form of a bell or buzzer. This novel learning situation is extremely difficult for the brain-impaired patient.

Another excellent general measure of cortical function is the Tactual Performance Test (TPT), which requires that the blindfolded patient place 10 different blocks in their proper place on a modified Seguin-Goddard form board by using first the dominant hand, then the nondominant hand, then both hands together. After the third trial, the patient is asked to draw the board from memory. Other Halstead-Reitan tests include the Speech-Sounds Perception Test, the Rhythm Test, the Finger-Oscillation Test, and Trails A and B. In addition, sensory-perceptual, lateral dominance, and aphasia examinations are included as part of the battery. Cutoff scores suggestive of brain impairment are provided for most tests, and the most sensitive tests are included in the calculation of the Impairment Index, a general measure of cortical dysfunction.

Somewhat different tests are included in two other versions of the Halstead-Reitan Battery that were developed for assessing younger and older children. The children's versions of the battery have not been as well validated as the adult battery.

Recent research on the Halstead-Reitan Battery has focused on head and brain injury, characterizing the types of neuropsychological deficits that occur, and identifying the similarities and differences in mild and more severe head injury. Development of knowledge in this area has added to the value of the Halstead-Reitan Battery, in both clinical evaluation and the area of forensic neuropsychology.

Interest in the Halstead-Reitan Battery continues to grow, spurred by a series of workshops given by Reitan and his colleagues. In addition, graduate students in clinical neuropsychology training programs routinely learn to administer and interpret the Halstead-Reitan Battery. Computer programs have been developed to interpret test results from the battery; these programs typically convert raw test scores into scaled and T scores. Because these programs use exact age and education values in calculating T scores, they may provide data that are more useful for the clinician than raw scores alone. Some researchers and clinicians have begun to supplement the traditional Halstead-Reitan Battery with additional tests such as the Boston Diagnostic Aphasia Examination and the Wisconsin Card Sorting Test.

In sum, it appears that the place of the Halstead-Reitan Battery is secure, both in the history of psychology and in the practice of neuropsychology.

HANDICAP

A handicap is a constellation of physical, mental, psychological, and/or social properties or processes that complicate adaptation, such that optimal development and functioning are not achieved. Other related terms such as *disability* or *impairment* are often used interchangeably; however, there has been a call for greater precision to decrease the stigma associated with various conditions. The World Health Organization (WHO) distinguishes the terms *impairment, disability,* and *handicap,* based on the manifestation of the disorder at the organic, whole-person, and societal level. Thus, *handicap* refers to the effect of a condition on an individual's functioning in a particular setting or situation: A paraplegic woman may be greatly handicapped on the dance floor but not handicapped in an accessible office setting. A handicap is the limitation imposed by social and psychological reactions to the condition. Thus, we maintain that a disability does not necessarily imply a handicap.

Handicaps associated less with a disability than with an individual difference help to clarify this distinction. Consider differences in visual functioning; individuals vary in terms of nearsightedness and farsightedness, and such visual impairment is often corrected with contact lenses or eyeglasses. An individual would be handicapped *only* if self-image were impaired, activity were restricted, visual information was distorted, or if others devalued the person for the impairment or prosthesis. At the same time it is possible that none of these "handicaps" would enter into the individual's adaptation *because vision problems are so common and so well accepted in our culture.* The same disability might be much more handicapping in a developing society where corrective lenses are unavailable.

Two major approaches to conceptualizing handicaps will illustrate the complexity of the transformation of a disability into a handicap. The dominant approach in both professional and lay culture uses disease metaphors for the individual differences represented by the disability. The disability is a negative property setting the individual apart from "normal" people, requiring medically oriented interventions such as diagnosis and treatment. Thus, there is something wrong with the individual, who is seen as needing treatment aimed toward curing, rehabilitating, or at least ameliorating the disability.

This medical orientation predominates in current professional practice and public policy. Its bias is inherent in most major classification systems currently available for categorizing disabilities and handicaps. For instance, the Federal Rehabilitation Act of 1973, Section 504, uses the term *handicap* to refer to a range of conditions including speech, hearing, visual, and orthopedic impairments and cerebral palsy, epilepsy, muscular dystrophy, multiple sclerosis, cancer, diabetes, heart disease, mental retardation, emotional or psychiatric disorders, drug or alcohol addiction, and specific learning disabilities. The particular domain in which the handicap presents can be indicated in a classification schema, as in the concept of educational handicaps—conditions that interfere with a child's academic achievement but have limited impact in other settings such as on the baseball field.

An alternative approach to conceptualizing handicaps considers the handicap a social construction rather than an inherent trait of the disabled individual. This approach maintains that a handicap is a social condition, created by society. A person's bodily or behavioral condition becomes a handicap only to the extent that other people, or the person himself, define it as such. The result of this social definition is to create distinctive environments and behaviors that sequentially remove the person from normal life patterns and, in time, convince all concerned that the person truly is handicapped.

Because most persons sense the social consequences of being different, great effort is exerted to avoid such characterization. Individuals may exert great effort to conceal their differences. These attempts to pass and cover, along with the substantial creations of society to cope with those who are different, provide extensive evidence for the need to examine handicaps as social conditions. This approach suggests directions for prevention and treatment of handicaps—directions that are antithetical to the current approaches of our educational and rehabilitation agencies, which require diagnosis or labeling in order to obtain services necessary to avoid turning a disability into a handicap.

Approaching handicaps as social constructions reveals parallels between handicapped persons and other minority or disadvantaged groups. Discrimination or prejudice against disabled individuals thus becomes a counterpart to racism and sexism, whether in its individual, institutional, explicit, or implicit forms.

The civil rights movement has recently made headway in increasing society's awareness of handicapped people. Legislation and court decisions have moved our society in the direction of more humanitarian and pluralistic approaches. The Rehabilitation Act of 1973, the Education for All Handicapped Children Act (Public Law 94-142), and the Americans with Disabilities Act of 1994 represent this major thrust toward guaranteeing educational, civil, and human rights for handicapped individuals, specifying governmental obligations for ensuring their psychological as well as physical well-being. Under the Americans with Disabilities Act, failing to fully include individuals with disabilities is forbidden, with civil penalties for individuals and institutions that discriminate on this basis.

Concepts and policies such as *deinstitutionalization, mainstreaming, inclusion,* and *normalization* form the basis of these approaches. *Deinstitutionalization* refers to efforts to remove the handicapped from segregated settings, provide for those with special needs in the community, and increase opportunities for optimal and normalized development. *Inclusion* is a newer version of mainstreaming,

based on including the disabled from the onset. *Normalization* is a similar concept, applied beyond educational settings, and emphasizes keeping disabled individuals integrated to the greatest possible extent.

HAWTHORNE EFFECT

The Hawthorne effect is named for a series of studies conducted from the late 1920s through the 1930s at the Western Electric Company's Hawthorne Works near Chicago. Many textbooks cite these studies as central in the historical development of industrial/organizational psychology. Introductory textbooks and experimental methods texts discuss the Hawthorne effect, although only rarely is reasonable attention given to the overall scope of this research program. Stated in its simplest form, the Hawthorne effect suggests that any workplace change, such as a research study, makes people feel important and thereby improves their performance.

Much of the credit for the Hawthorne studies is often given to F. J. Roethlisberger and W. J. Dickson, who in 1939 published a major book describing the research. As described by them, the Hawthorne studies had five distinct research phases: the illumination experiments, the relay assembly test room experiments, the mass interviewing program, the bank wiring observation room experiments, and the program of personnel counseling.

The illumination experiments had the initial purpose of relating levels of lighting to worker productivity. A number of specific studies were done, but no clear functional relationship could be found between the two variables. Indeed, throughout these illumination studies, the researchers attempted to improve experimental control, apparently believing a well-designed study would answer their question.

The second major phase of the Hawthorne studies was an attempt at studying workers' performance under carefully controlled conditions. For this purpose, five employees were selected and isolated in a separate room, along with a layout operator (i.e., a person who assigns work) and a research observer. In this setting a number of experiments were performed, mostly focusing on differing schedules of rest breaks. Although it is often reported that all experimental conditions in the relay assembly test room led to improved production over the preceding condition, such an interpretation is misleading. Two individuals showed a general tendency to improve production; one showed steady production overall; but two others showed generally decreasing production and so were replaced by more "cooperative" employees. Clearly, the overall trend toward improved production does not necessarily apply to individual workers.

At the completion of the relay assembly test room studies, the researchers began to realize that more was involved than the physical conditions of work. Specifically, it was apparent that the social impact of the research was far greater than the impact of changes in lighting or rest breaks. To clarify this issue, the mass interviewing program was begun. In the following years over 20,000 employees were interviewed.

The fourth phase of the Hawthorne studies grew out of the mass interviewing program. Given the importance of social groups in the workplace, the bank wiring observation room studies were designed as an intensive investigation of such groups. To perform this investigation, 14 men were observed and interviewed for over 6 months, which produced a wealth of data on work groups.

Finally, the fifth phase involved an extensive program of personnel counseling. Counselors were employed who could be approached by employees and confided in as impartial agents. With the opening of such communication channels, supervisors could be assisted in improving their behavior. In general, the researchers reported a number of improvements in intraorganizational communication.

A simplistic view of the Hawthorne effect is unwarranted. Clearly, not everything the experimenters tried led to improved productivity, although the Hawthorne effect is often described in precisely such terms. What is clear, however, is that changes in lighting or rest breaks could not by themselves explain changes in employee performance.

Given the apparent complexity of the Hawthorne effect, a number of people have tried to clarify its nature. Robert L. Kahn has pointed out that the Hawthorne effect cannot be counted on to emerge from all research studies. His analysis suggests that worker participation in important decisions plays a major role in eliciting the effect.

Another approach is taken by H. McIlvaine Parsons, who suggests that principles of operant conditioning and reinforcement can best explain the results of the Hawthorne studies. In this view, day-to-day feedback, combined with an appropriate reward structure, is critical in shaping the behavior of workers.

A third view of the Hawthorne studies suggests that traditional interpretations of these studies rely on the unjustified assumption of capitalist philosophy. These criticisms see the Hawthorne studies from a socialist perspective and suggest that the traditional interpretation is a myth.

It has recently been shown that there are ways to actually increase the likelihood of obtaining the Hawthorne effect. Many action researchers have the goal of bringing about positive changes in such measures as performance, and using goals and feedback and removing obstacles to performance indeed makes positive change more likely.

Regardless of one's personal theoretical orientation, it is clear that the Hawthorne studies constitute an important

milestone in industrial/organizational psychology. Certainly, a wealth of data were collected, and although they have long been recognized as imperfect, the studies are still important to consider.

HEAD START

Head Start is a comprehensive intervention program for young children and their families who live in poverty. It is the largest and longest-running federal program established to prepare this population for a successful entry into elementary school. As such, it has served as a national laboratory for the design, study, and refinement of effective intervention techniques.

Head Start was conceived as part of President Lyndon Johnson's War on Poverty—a national campaign to enable the poor to improve their status through self-help and educational opportunities. Whereas most of the war efforts targeted poor adults, Head Start was envisioned as a program to help poor preschoolers begin school on an equal footing with children from wealthier homes. However, with the exception of a few experimental projects, there was little experience or research evidence to suggest how to bolster their school readiness. Johnson's chief strategist in the war, Sargent Shriver, convened a panel of experts in education, physical and mental health, social work, and developmental psychology to design the new program. The group's professional diversity gave Head Start more than a strictly educational focus.

The committee's recommendations were presented to Shriver in February 1965, just a few months before the program was to open its doors. The planning document was based on a "whole child" philosophy that embraced a variety of objectives related to school readiness. Children were to receive inoculations, physical and dental exams, and follow-up treatment if needed. They would eat hot meals and nutritious snacks, and their parents would be taught to provide healthy diets at home. The preschool education component would be developmentally and culturally appropriate, including language and other academic skills as well as experiences to promote social and emotional development. Parents would volunteer in the classrooms, attend classes of their own, and have a role in program administration. Family needs and goals would be assessed and support services provided through the program and links to community agencies. Head Start would develop community partnerships to enhance the availability and delivery of human services. The need for these components was an educated guess at that time but has now proved critical to the success of early intervention.

Head Start opened in the summer of 1965, serving over half a million children and their families. Today the program is housed in the Head Start Bureau in the Administration on Children, Youth and Families. In fiscal year (FY) 2001, over 905,000 children attended Head Start in some 48,500 classrooms nationwide. The majority are 3- and 4-year-olds whose parents have incomes below the federal poverty line. About 13% are children with disabilities. The FY 2002 budget was about $6.5 billion, which allowed the program to serve about half the eligible children (estimates vary). By law, grantees receive 80% of their funding from the federal government and the rest from other, usually community sources.

Each Head Start center must focus on three major activities: child development services (physical and mental health, nutrition, preschool education); family and community partnerships (including parent involvement and social support services); and program design and management (to improve quality and accountability). Although these components must conform to a national set of performance standards, centers are encouraged to adapt their services to local needs and resources. For example, some programs offer home-based services, and an increasing number are extending hours or collaborating with local child care providers to accommodate children whose parents work. Thus it is somewhat misleading to think of Head Start as a single intervention because of the variety in local programming.

Head Start's early administrators never believed that this brief preschool experience would end poverty. They dismissed the then-popular "inoculation model," which held that some quick fix could make up for the past and prevent the future effects of growing up in economically disadvantaged conditions. They encouraged the development of dovetailed programs to serve children and families both before and after the preschool years. A recent example is the Head Start/Public School Early Childhood Transition project, which continued parent involvement and comprehensive services to preschool graduates through third grade. Studies of this and similar programs have shown that extending services into elementary school benefits children's achievement and adaptation. All Head Start programs are now mandated to undertake transition to school activities at least until the young students are settled in their new environment.

Efforts to serve children before the preschool years also began early in Head Start's mission. Mounting evidence that preventive efforts are more effective than remedial ones, and that waiting until a child is 3 or 4 years old is sometimes too late, spurred political support for interventions for very young children. In 1994, congress authorized Early Head Start for families and children from birth to 3 years. Services begin prenatally and include health care,

nutrition, parenting education, and family support services. In FY 2001, there were 650 such programs serving over 55,000 infants and toddlers. Initial evaluations have shown many developmental benefits to this approach.

Early evaluations of preschool Head Start focused almost entirely on improvements in children's intelligence. This outcome was highlighted both because the project's goals outlined in the planning document were not very specific and because psychologists in the 1960s were enthralled with the possibility that IQ scores could be raised substantially. The results of such research on Head Start and just about every other early intervention arrived at the same conclusion: IQ scores do increase during preschool (later found to be due to better motivation and familiarity with the testing situation), but these gains fade out after a few years in elementary school. When researchers looked at broader outcomes, they found more lasting benefits. Quality preschool programs raise school achievement, reduce grade repetition and special education placements, and appear to reduce later juvenile delinquency. A major study currently underway is the Family and Child Experiences Survey (FACES), which is following the progress of former Head Start students and their families as well as analyzing qualities of the preschool programs they attended. Results thus far show that Head Start graduates are ready for kindergarten and better able to benefit from later schooling.

Research on Head Start's preschool, demonstrations, and the model programs it inspired has created a large knowledge base on early childhood care and education that did not exist in its founding days. Children who are healthy, have the social and academic skills they need, have parents who are involved in their education, and have families whose basic needs are met are more competent when they arrive at school. To help them attain school readiness, programs must be comprehensive, of high quality, and of long enough duration to make a meaningful difference.

HEADACHE

Headache is one of the most common pain complaints. Over the 10-year period from 1987 to 1996 health care providers saw an increasing number of individuals with pain-related diagnoses, primarily due to an increase in the number of patients with headache.

Description of the Major Types of Headache

Migraine headache is episodic and characterized by a throbbing, pulsating, or pounding type of pain that generally starts on one side of the head, although, as the headache progresses, it often encompasses both sides. It typically starts over an eye or in the temple region and can last anywhere from 2 hours to 3 days. Frequently it is accompanied by nausea and, sometimes, vomiting, as well as sensitivity to noise (termed *phonophobia*) and, especially, light (termed *photophobia*). A migraine can occur on a frequency of two a week to only one or two a year; the average migraineur has one to two headaches a month. Approximately 10% of migraine headache patients have a prodrome—that is, preheadache symptoms that can occur up to 30 minutes before a headache, such as seeing flashing lights or squiggly lines, experiencing a disturbance in speech, or experiencing a tingling, burning, or pricking feeling in the arms or hands (termed *paresthesia*). Those migraine headache sufferers with a prodrome are described as *classic migraineurs;* those without a prodrome are termed *common migraineurs.*

Migraine headache is predominantly a disorder of women during the childbearing years. In prepubertal children, migraine is approximately equally distributed across the sexes. With the onset of menarche, females begin to outnumber males by about 2 or 3 to 1.

Tension headache is generally less episodic and is characterized by a steady, dull ache or pressure that is generally on both sides of the head. It is sometimes described as a tight band or cap around the head, a soreness, or a nagging or vicelike pain. It typically begins in the forehead, temple, back of the head and neck, or shoulder regions, and encompasses the entire head. A tension headache can last from 30 minutes to 7 days. If headaches occurs less than 15 days a month, they are termed *episodic tension-type headache;* if the headaches are experienced 15 or more days a month, they are termed *chronic tension-type headache.* The pain associated with tension headache is considered to be of generally lesser intensity than that of migraine headache. Tension-type headache is believed to be the most prevalent form of headache. It is more common in females than males, with a male to female ratio of approximately 1:1.5. Age of onset is generally in the second decade, and it peaks between the ages of 30 and 39.

Up to half of patients with migraine headache also meet the criteria for tension headache. These individuals have been labeled as *mixed migraine and tension-type headache* or *combined migraine and tension-type headache.* Most clinicians and researchers have typically lumped both pure migraine and mixed migraine and tension headaches together under the label of vascular headache and treated them similarly. Cluster headache, which is a very rare type of headache and tends to be found predominantly in males, is generally diagnosed by its very distinctive temporal pattern: In episodic cluster headache, the patient is headache-free for months to years and then enters a so-called cluster bout. During the cluster bout, the one-sided headaches appear fairly regularly, once or twice per day to every other day. The headaches are described as intense, excruciating

pain, as if someone is drilling or boring into the head, that often makes it impossible for the patient to lie still. They last from 15–30 minutes to 2–3 hours. Many patients are so debilitated by this type of headache that it can take hours after the cessation of pain for them to return to a normal level of functioning. The cluster bout lasts several weeks to several months and then disappears. Some poor unfortunates have continuous cluster headaches.

Psychological Treatment Outcome of Headache

A beneficial manner of reporting outcome is the average proportion or fraction of a sample of headache patients who achieve a clinically significant reduction in headache activity, as documented by a daily headache diary. In chronic pain, a patient with 50% or greater reduction in pain activity has traditionally been considered a treatment success.

The three primary psychological approaches to headache are relaxation therapy, biofeedback, and cognitive-behavioral therapy. Because they are felt to have both psychological and physiological effects, the first two approaches are frequently called *psychophysiological interventions.* In practice, they are often combined with each other as well as cognitive-behavioral therapy. Please refer to the appropriate sections of this encyclopedia for more detail concerning these treatments.

Tension Headache

With tension headache, the biofeedback approach used is electromyographic (EMG; muscle tension) feedback from the forehead, neck, and/or shoulders. For relaxation therapy alone, successful treatment outcomes generally range from 40 to 55%; for EMG biofeedback alone, this value ranges from 50 to 60%, and for cognitive therapy, from 60 to 80%. When EMG biofeedback and relaxation are combined, the average number of treatment successes improves from about 50 to about 75%; when relaxation and cognitive therapy are combined, success increases from 40 to 65%.

Migraine Headache

For patients with pure migraine headache, hand surface temperature (or thermal) is the biofeedback modality of choice, and it leads to clinically significant improvement in 40 to 60% of patients. Cognitive therapy by itself achieves about 50% success. A systematic course of relaxation training seems to help when added to thermal biofeedback (increasing success from about 40 to 55%), but cognitive therapy added to the thermal biofeedback and relaxation does not improve outcome on a group basis. Relaxation training alone achieves success in from 30 to 50% of patients, and adding thermal biofeedback boosts that success (from about 30 to 55%).

Combined Migraine-Tension Headache

For patients with both kinds of the primary benign headache disorders (migraine and tension-type), the results with thermal biofeedback alone are a bit lower, averaging 30–45% success; relaxation training alone leads to 20–25% success. The best results come when thermal biofeedback and relaxation training are combined. With this combination treatment, results show 50–55% success rates (adding thermal biofeedback to relaxation raises success from 20 to 55%; adding relaxation therapy to thermal biofeedback increases success from 25% to 55%). Most experts strongly recommend a combination of the two treatments for these headache sufferers.

Cluster Headache

Nonpharmacological interventions have been found to be relatively ineffective for cluster headache, and many practitioners no longer see such patients in their practice.

Special Headache Populations

There is now a sizable body of research attesting to the efficacy of thermal biofeedback with pediatric migraine. In addition, headaches in the elderly can also be effectively treated with biofeedback and relaxation techniques, as can those individuals who consume excessive levels of medication. A number of investigators have demonstrated that a combination treatment including relaxation therapy and biofeedback is efficacious for treating headaches during pregnancy. Because pregnant women are not able to use most pain medications, many experts have suggested that techniques such as the psychophysiological interventions and psychotherapy should be the first-line intervention for headaches during pregnancy.

HETEROSEXUALITY

Sexual Behavior

The idea that sex is strictly for reproduction has deep historical roots in Western culture. Early Christian writers such as Thomas Aquinas promoted the view of sex as sinful, justifiable only in marriage for the purpose of procreation. Greater knowledge, technical advances in contraception, media awareness, and legal decisions have allowed

people to separate sexuality from procreation and make personal decisions regarding sexuality. Variations in ethnicity, acculturation, religious orthodoxy, and socioeconomic status account for great diversity in sexuality. Human sexual behaviors cluster primarily around kissing and touching, intercourse (vaginal, anal), oral-genital stimulation, and masturbation. Atypical sexual behaviors, those behaviors that fall outside this range, include noncoercive paraphilias such as fetishism, transvestism, sexual sadism, and sexual masochism, and coercive paraphilias such as exhibitionism, voyeurism, frotteurism, necrophilia, and zoophilia. Because paraphilic behaviors are typically a source of intense sexual pleasure, individuals are generally reluctant to seek treatment and psychotherapy has not proven to be highly effective.

Sexual Response

Sexual Desire

Sexual desire refers to the broad interest in sexual objects or experiences and is generally inferred by self-reported frequency of sexual thoughts, fantasies, dreams, wishes, and interest in initiating and/or engaging in sexual experiences. Definition of this construct is complicated by factors such as attitudes, opportunity/partner availability, mood, and health. Relationship factors, individual preferences for sexual variety and emotional intimacy are closely linked to sexual desire. Androgens appear to also play a role. In males, about 95% of androgens (e.g., testosterone) are produced by the testes; the remainder is produced by the outer adrenal glands. In females, androgens are produced by the ovaries and adrenal glands in quantities much lower than in males (about 20–40 times less; Rako, 1996). In both males and females, decreased testosterone levels due to, for example, orchidectomy (removal of testes) or oophorectomy (removal of ovaries) have been linked to impaired sexual desire.

Sexual Arousal

Closely connected with desire, sexual arousal is defined in both subjective (e.g., feeling sexually excited) and physiological terms (e.g., genital vasocongestion). The primary markers of sexual arousal in both sexes are increased myotonia (muscle tension), heart rate, blood pressure, and vasocongestion (blood engorgement), which leads to penile erection in males, and engorgement of the clitoris, labia, and vagina (with lubrication) in females.

Physiological sexual arousal in males involves signal input from the brain and spinal cord and peripheral nervous systems, and on a complex interplay between neurotransmitters, vasoactive agents, and endocrine factors. Within the penis is a central artery (corpus cavernosum) and veins that exit and drain the erectile bodies. The muscles that line the sinusoidal spaces and the central artery are contracted during the nonerect state. Erection begins with muscle relaxation that is controlled by autonomic nerves and by the release of nitric oxide into the corpus cavernosum. Cyclic guanosine monophosphate (cGMP) mediates the effects of nitric oxide, which causes smooth muscle relaxation, reduces vascular resistance, and allows the erectile bodies to fill with blood. Once the erectile bodies become engorged, the veins are compressed under the penis's tough fibroelastic covering and blood is trapped in the penis. Normally, detumescence (loss of erection) occurs with the release of catecholamines during orgasm and ejaculation.

Physiological sexual arousal in women begins with vasocongestion of the vagina, vulva, clitoris, uterus, and possibly the urethra, and can occur within only a few seconds of sexual stimulation. Vaginal lubrication occurs when the blood vessels of the vaginal wall become engorged with blood, causing fluid to pass between the cells of the vaginal epithelium and emerge on the vaginal wall as sweatlike droplets. These droplets can quickly build up to form a lubricating film that facilitates penetration of the penis. Estrogens, produced predominantly by the ovaries, help maintain the elasticity of the vaginal lining and assist in vaginal lubrication.

Orgasm

In males and females, orgasm is characterized by a peak in sexual pleasure that is accompanied by rhythmic contractions of the genital and reproductive organs, cardiovascular and respiratory changes, and a release of sexual tension. In males, orgasm generally occurs in two stages: emission, which refers to rhythmic muscular contractions that force semen into the ejaculatory ducts, and expulsion, which is the release of semen through the urethra (ejaculation). Unlike males, some females (approximately 15%) are able to experience multiple orgasms, and some women experience orgasm and perhaps ejaculation when the Grafenberg spot, an area along the anterior wall of the vagina, is stimulated. Contrary to Freud's assertion of two distinct types of orgasm in females, clitoral (the "infantile" orgasm) and vaginal (the "mature" orgasm), Masters and Johnson (1966) found no physiological differences in orgasm produced by vaginal versus clitoral stimulation. Other researchers note that intensity of orgasm and emotional satisfaction can differ dependent upon type of stimulation.

Resolution

Following orgasm, physiological responses return to the unaroused state. In males there is a refractory period, a period of time in which it is physiologically impossible to achieve another orgasm. The length of the refractory period is highly variable and depends upon a number of fac-

tors including age, novelty of sexual situation, and frequency of sex. The extent to which aging affects the sexual response in both males and females depends largely on psychological, pharmacological, and illness-related factors.

Sexual Dysfunction

Diseases of the neurological, vascular, and endocrine systems (e.g., diabetes, cancer, multiple sclerosis) can impair virtually any stage of the sexual response. Medications used to treat depression, high blood pressure, psychiatric disorders, and cancer, as well as numerous recreational drugs (e.g., barbiturates, narcotics, alcohol abuse, tobacco smoking) can interfere with sexual desire, arousal, and orgasm. Psychological factors contributing to impaired sexual function most commonly include anxiety, relationship concerns, negative attitudes about sex, religious inhibition, and fears of pregnancy.

Low or absent sexual desire (hypoactive sexual desire) is the most common problem of couples going into sex therapy. Approximately 33% of women and 15% of men ages 18–59 report a lack of sexual interest (Laumann, Gagnon, Michael, & Michaels, 1994). Sexual aversion disorder is an extreme, irrational fear or dislike of sexual activity that leads to the avoidance of all or nearly all genital sexual contact with a sexual partner. Arousal difficulties include female sexual arousal disorder—inhibition of the vasocongestive/lubrication response—and male erectile disorder. Women of all ages may experience difficulty with lubrication, although it tends to be a problem more associated with menopause. Erectile problems may be of organic (e.g., circulatory problems, neurological disorders, hormone imbalances) or psychogenic (e.g., performance anxiety) origin. The ability to have erections during REM sleep suggests that the problem is psychological. Approximately 7% of men ages 18–29 years, and 18% of men ages 50–59 years, experience erectile difficulties (Laumann et al., 1999). *Anorgasmia,* which occurs in approximately 24% of women ages 18–59 (Laumann et al., 1999), refers to the inability to attain orgasm. *Premature ejaculation* is defined as ejaculation early on in the sexual scenario and before the person wishes it, and is reported in approximately 29% of men ages 18–59 years (Laumann et al., 1999). *Dysparuenia,* or pain during intercourse, occurs most commonly in females, and generally involves a combination of physical and psychological factors. *Vaginismus* is characterized by involuntary contractions of the muscles in the outer third of the vagina that interfere with penetration of the vagina (e.g., during intercourse, insertion of fingers, tampons, gynecological exam).

HIPPOCAMPUS

Ever since Scoville and Milner's 1957 report on the patient H. M., who suffered a profound amnesia following bilateral surgical resection of the medial temporal lobe, it has been clear that the hippocampal region of the brain plays a critical role in memory. There is now considerable knowledge about the anatomical pathways of the hippocampus, about the functional role of the hippocampal region, and about the information encoded by firing patterns of hippocampal neurons.

Anatomy of the Hippocampus

From the perspective of its role in cognition and memory, the hippocampal system is last in a long succession of stages of cortical representation (Van Hoesen, 1982). Neocortical areas that provide information to the hippocampal system include only the highest stages of each neocortical sensory system, plus multimodal and limbic cortical areas and the olfactory cortex. These inputs arrive in three main cortical subdivisions of the parahippocampal region, composed of the perirhinal, parahippocampal, and entorhinal cortices. Superficial layers of parts of the parahippocampal region then project onto the hippocampus itself at each of its main subdivisions.

The main flow of information through the hippocampus involves serial connections from the dentate gyrus to CA3 to CA1, and then to the subiculum (Amaral & Witter, 1989). The intrinsic hippocampal pathway partially preserves the topographical gradients of neocortical input, but there are also considerable divergence and associational connections, particularly at the CA3 step. Outputs of subiculum, and to a lesser extent CA1, are directed back to deep layers of the parahippocampal region, which in turn projects back onto the neocortical and olfactory areas that were the source of cortical inputs. Thus, the hippocampal system is organized for maximal convergence of the final outcomes of cortical processing and is positioned to influence the nature of cortical representations based on an architecture ideal for the formation of associations among them.

Human Amnesia and Animal Models of Hippocampal Function

The early findings on H. M. emphasized the global nature of his impairment, an almost complete failure to learn all sorts of new verbal and nonverbal material (see Corkin, 1984; Eichenbaum & Cohen, 2001). Yet H. M.'s remote autobiographical memories and his capacity for short-term memory were completely intact, leading to the initial view that the hippocampal region plays a specific role in the consolidation of short-term memories into long-term memory. More recent work with H. M. and other amnesic patients has shown conclusively that the impairment in acquiring long-term memories is also circumscribed to a particular type of memory expression. Thus, amnesics can normally acquire new motor, perceptual, and cognitive skills and demonstrate normal sensory adaptations and "priming" of perceptual stimuli; and such implicit learning occurs despite the patients' inability to recall or recognize the learning materials or the events of the learning experience. Based on these distinctions, the kind of memory lost in amnesia has been called *declarative* or *explicit* memory, emphasizing the characteristic capacity for conscious and direct memory expression so devastated following damage to the hippocampal region. Conversely, the collection of capacities preserved in amnesia has been called *procedural* or *implicit* memory, emphasizing the finding that hippocampal-independent memories are characteristically revealed by unconscious and indirect means of expression.

Considerable success has been achieved in developing nonhuman primate and rodent models of human amnesia. Following removal of the same medial temporal structures involved in H. M.'s surgery, monkeys are severely impaired on delayed recognition of objects and show poor retention of rapidly acquired object discriminations. Conversely, they have a preserved ability to acquire slowly learned motor skill and pattern discrimination tasks. In addition, hippocampal damage results in impaired retention of object discriminations learned shortly before the lesion but spares retention of similar discriminations learned long before the damage. These findings parallel the pattern of impaired and spared memory capacities observed in human amnesics.

Further findings from experiments on monkeys and rats that focused on more selective damage within the medial temporal lobe suggest that the surrounding parahippocampal region and the hippocampus may play different roles in memory processing. Selective damage to the hippocampus results in either no deficit or only a mild deficit in recognition memory for specific objects, whereas damage to the parahippocampal region results in a severe impairment. By contrast, damage to either the hippocampus or the parahippocampal region results in impairments in linking memories to support flexible, inferential memory expression. According to one model the parahippocampal region may act as an intermediate-term buffer for convergent perceptual representations, whereas the hippocampus associates these representations into the network of long-term memories (Eichenbaum, 2000).

Information Encoded By Hippocampal Neurons

Complementary evidence on the nature of memory processing accomplished by the hippocampus has been derived from studies of the firing patterns of hippocampal neurons in behaving animals. Consistent with the view that the hippocampus is the ultimate stage of hierarchical processing, the functional correlates of hippocampal cells are "supramodal" in that they appear to encode the abstract stimulus configurations that are independent of any particular sensory input. Most prominent among the functional types of hippocampal principal neurons are cells that fire selectively when a rat is in a particular location in its environment as defined by the spatial relations among multiple and multimodal stimuli (O'Keefe, 1976). In addition, there are many reports of nonspatial behavioral correlates of hippocampal neuronal activity that indicate that hippocampal representation is not limited to the encoding of spatial relations among distal cues (e.g., Wood, Dudchenko, & Eichenbaum, 1999). Even the activity of place cells is influenced by events that are meaningful to the task at hand (e.g., Wood, Dudchenko, Robitsek, & Eichenbaum, 2000). These findings extend the range of hippocampal coding to reflect the global involvement of the hippocampus in memory indicated by the neuropsychological studies and serve to reinforce the conclusion that the hippocampus supports relational representations (Eichenbaum, Dudchenko, Wood, Shapiro, & Tanila, 1999).

A comprehensive and consensual understanding of the role of the hippocampal system in memory remains elusive. Nevertheless, there is an increasing convergence of evidence indicating that the hippocampus represents and relates specific experiences into a network of memories that supports our capacity for declarative memory.

HISTORY OF CLINICAL PSYCHOLOGY

Clinical psychology is probably the most common specialty within psychology around the world today (Lunt & Portinga, 1996). Its principal aims include the study of psychopathology and its assessment and treatment. This same territory is shared by a number of other professional disciplines, including psychiatry, social work, mental health nursing, and various types of counseling. Compared to professionals in these neighboring fields, present-day clinical psychologists are distinctive in the quality of their training in research, psychometric testing, and behavior therapy.

Within the Western tradition, the earliest influential concepts of psychopathology are those found in the writings attributed to the Greek physician Hippocrates (c. 460–377 b.c.e.), who viewed madness as an illness like any other (Routh, 1998). For example, Hippocrates identified the condition called melancholia as being due to an excess of black bile produced by the pancreas (the very word *melancholia* means "black bile"). Such an imbalance of the internal fluids, or "humors," was treated by administering purgatives, whereas a furious manic state was more likely to be treated by bleeding the patient.

The specialty of psychiatry did not develop until the eighteenth century, and it did so simultaneously in a number of different countries, including England, Italy, France, and the new United States of America. The most famous figure of this era was the physician Philippe Pinel (1745–1826), who was in Paris at the time of the French Revolution. He elaborated the principles of moral treatment of mental patients. The basic idea was that it was not necessary to chain a mental patient to the wall. Instead, one should treat the individual in a kind and considerate way, minimizing coercion. It was during this time that asylums began to be considered as a way of treating the insane and not simply a way of confining them to protect society. In 1838, a French law was passed creating a national system of asylums. Soon afterward, formal organizations of "alienists," or psychiatrists, developed and began to publish scholarly journals. For example, the organization that became the American Psychiatric Association was founded in 1844.

In 1896, a psychological clinic was founded at the University of Pennsylvania by Lightner Witmer (1867–1956), a professor there. This event is generally regarded as the origin of the field of clinical psychology. Witmer, who had obtained his doctorate under Wundt, was especially interested in children with learning problems, including those in reading and spelling as well as general academic retardation. What was especially new was his suggestion that psychologists not only study people but also attempt to help them. He used the techniques being developed by experimental psychologists to study children and worked with teachers, physicians, and others to try to remediate such problems. Witmer trained doctoral students in these activities, and in 1907 founded a journal, *The Psychological Clinic,* in which he outlined his ideas concerning the new field (Witmer, 1907).

In France in 1905, the experimental psychologist Alfred Binet (1857–1911) and a physician, Theodore Simon (1873–1961), developed the first successful intelligence test. This test was quickly translated into English and imported by the United States, where it soon underwent various technical refinements by Lewis M. Terman (1877–1956) and became the Stanford-Binet (Terman, 1916). Administering Binet tests became the most characteristic activity of the first generation of clinical psychologists in the United States. For example, psychologists were incorporated into the clinical team of the first child guidance clinics primarily as intelligence testers. In 1908, psychologist Henry Goddard founded the first psychology internship program at the Vineland School in New Jersey; the program mainly provided extensive experience in such mental testing. The first organization of clinical psychologists, the American Association of Clinical Psychologists, founded in Pittsburgh in 1917, had as one of its purposes the staking out of individual mental testing as the professional domain of clinical psychologists (Routh, 1994).

Before World War II, clinical psychology was a small field. However, even before 1945, the repertoire of clinical psychologists in the area of mental testing expanded greatly, establishing its pattern for the remainder of the century. Herman Rorschach (1884–1922), a Swiss psychiatrist, developed the Rorschach inkblot test. In 1943, psychologist Starke R. Hathaway (1903–1984) and psychiatrist J. C. McKinley published the first edition of the Minnesota Multiphasic Personality Inventory. The *Journal of Consulting Psychology,* now one of the premier journals in clinical psychology, was established in 1937; during its first decade, it was devoted largely to professional issues and to advances in mental testing.

After World War II, clinical psychology was newly supported by government funds and expanded enormously. In the United States, the Veterans Administration and the National Institute of Mental Health requested information about which universities provided adequate training in clinical psychology. The American Psychological Association responded by setting up an official system for accrediting training in clinical psychology. In 1949, the Boulder Conference set the pattern for such programs, which sought to train "scientist-practitioners." In Britain and on the European continent, clinical psychologists began to be incorporated into the national health systems of many countries.

In this era, clinical psychologists have generally expanded their scope of practice beyond mental testing to include various intervention activities. In the postwar United States, the most influential clinical psychologist involved in psychotherapy was no doubt Carl R. Rogers (1902–1987). Other psychologists, such as Hans Eysenck (1916–1997) in Britain, launched the behavior therapy movement.

In conclusion, clinical psychology has emerged from its first century of existence as the largest psychological specialty, with a focus on the study, assessment, and treatment of psychopathology.

HISTORY OF PSYCHOLOGICAL ASSESSMENT

It can be assumed that early humans, well back into prehistory, engaged in informal evaluations of their fellows on such psychological variables as intelligence, aggressiveness, and cooperativeness. In the ancient world, after the dawn of civilization, the two primary methods of systematic assessment were horoscopic astrology and physiognomy. Astrology had the appeal that it was not necessary for the assessor to actually see the subject in order to provide a personality description; its disadvantage was that it was totally invalid, although this was not readily apparent. Physiognomy, based on the subject's physique and style of movement, though also grossly invalid, had at least the advantage that the assessor saw the subject.

Both astrology and physiognomy were immensely popular during the medieval and early Renaissance periods. However, in the latter period, in 1575, in Spain, there appeared a book that proposed the first rational, although still highly tentative, approach to assessment. This was Juan Huarte's *Examen de Ingenios para las Ciencas,* translated into English as *The Tryal of Wits.* Huarte argued that different persons have different talents ("wits") and that these differences are by measurable by experts ("Triers").

In 1691 Christian Thomasius, in what is now Germany, developed a primitive observational system for evaluating individual personalities, and reported quantitative data on several subjects, the first such instance in the history of psychology.

It was in the latter nineteenth century, however, in the person of Francis Galton, in England, that the movement toward scientifically based assessment got genuinely under way. Galton, who was something of a polymath, was passionately interested in measuring and calculating (he was the primary developer of the correlation coefficient) human individual differences. His 1883 book, *Inquiries into Human Faculty and Its Development,* presented a wealth of data on human attributes and capacities.

Although Galton employed the term *test* in something like its present sense, the word became more clearly established in the assessment lexicon by virtue of an important 1890 article, "Mental Tests and Measurements" by James KcKeen Cattell, an American who had spent some time in Galton's laboratory.

The breakthrough to a reasonable degree of accuracy in assessment was in the area of intelligence. In 1904, in Paris, a commission was appointed to devise a method for identifying children to be assigned to special classes. To help in such decisions Alfred Binet and Theodore Simon put together a series of 30 items varying in difficulty (e.g., 1: coordination of head and eyes in following a lighted match; 30: distinguishing between abstract terms) to indicate a child's level of mental development. The Binet-Simon scale proved useful, and later revisions were adopted and improved by others. The most prominent of these was the revision by Lewis M. Terman at Stanford, in 1916. This test—the Stanford-Binet—included the innovation of the intelligence quotient, or IQ (mental age divided by chronological age times 100). The concept of IQ became a part of American culture, as it still is, despite many technical problems that have since appeared.

An early problem with Binet-like tests was that they were not applicable to children with limited verbal skills. In response, psychologists early in the twentieth century developed several performance tests, including the Porteus Maze Test, the Kohs Block Design Test, and the Goode-

nough Draw-a-Man Test, to assess intelligence. In the same period Arthur S. Otis, an associate of Terman, developed the first of numerous pencil-paper tests roughly measuring intelligence in adults.

The Stanford-Binet had been specifically designed for the individual assessment of children. There was a need, however, for an equally precise measurement for adults. This need was met in 1939, with the publication of David Wechsler's Weschsler-Bellevue Intelligence Scale. Since then numerous additional tests for the assessment of intelligence have been developed. However, the Stanford-Binet and the Wechsler-Bellevue Scales, for both of which recent revisions have appeared, remain the most prominent.

The development of instruments for the assessment of personality and/or psychopathology did not lag far behind. Among the early personality questionnaires were R. S. Woodworth's Personal Data Sheet (used in the first World War to help identify unstable American soldiers); the Bernreuter Personality Inventory; and the Minnesota Multiphasic Personality Inventory (MMPI) by Starke Hathaway and Jovian McKinley in 1943. This latter test proved to be extremely useful and is still a part of the standard assessment armamentarium (it was revised in 1989).

Another early step in personality assessment was the construction of projective techniques (the subject is conceived to unknowingly "project" authentic personality traits into responses). The earliest—and still most popular—of these were the Rorschach and the Thematic Apperception test (TAT). The former instrument, created in 1921 by Herman Rorschach, a Swiss psychiatrist, consists of 10 inkblots in which the subject, reacting imaginatively, "sees" various objects. The interpretive system now most used is that of John E. Exner. The TAT, devised by Christiana Morgan and Henry Murray, consists of various pictures, to some of which the subject reacts by telling stories. Although numerous additional projective tests have since been constructed, the Rorschach and the TAT are still the most prominent.

Psychological assessment frequently includes systematic evaluations of a person's interests. The most important pioneer in this area was Edward K. Strong, a colleague of Terman's at Stanford in the 1920s. Another important area is achievement testing; this was pioneered by Edward Thorndike at Columbia and Terman at Stanford.

Currently, the field of psychological assessment is a thriving, active area. Numerous important new instruments have come to the fore: for example, in personality assessment, the California Personality Inventory, by Harrison Gough, and the Personality Assessment Inventory by Leslie C. Morey. In addition, there have been important new theoretical directions. One of these is behavioral assessment, in which the emphasis is on direct, systematic observation of the subject, rather than on psychological tests. Another new emphasis is on the use of structured interviews, particularly in the assessment of psychopathology. Also, significant advances have been made in neuropsychological assessment. Finally, computer technology is increasingly utilized in assessment, both in test administration and test interpretation.

HOMELESSNESS

Widespread homelessness is an age-old social problem, and a challenge to overcome.

What Is Homelessness?

Homelessness is more than the absence of a permanent address. It is a condition in which a very large and growing portion of people in the United States and most likely the rest of the world find themselves. It means being cut off from relatives, social groups, and community organizations and losing a sense of belonging to society.

Who Are the Homeless?

The homeless come from all walks of life, but the majority are single men. Among them are unemployed as well as the working poor whose average monthly income is $267.00. They are relatively young and disproportionately from minorities (e.g., Blacks, Hispanics) and die at an average age of 50. Among the rapidly growing homeless are single women, adolescents, and families with children. War veterans constitute one of the largest homeless contingents. Over a quarter of those who are homeless have achieved more than a high school education.

Causes

Poverty, unemployment, or other economic conditions may lead to homelessness. Underlying causes of homelessness are extreme poverty and a dearth of affordable housing. Nearly 1 in 5 homeless women and men cite gambling as a cause of their situation.

Large numbers of the homeless have alcohol, drug, or

mental disorders. It is not certain whether these disorders have come about before, during, or after homelessness. Substance Abuse is not considered to be either the cause or the consequence of homelessness, but rather a preexisting condition aggravated by loss of housing.

According to the *single calamity hypothesis,* homelessness grows out of a single crisis. Consequently, it would be difficult to predict which individual characteristics, experiences, and behaviors lead to homelessness. An individual crisis that occurs often to the homeless is a major illness. Thus, the onset of poor health may lead to homelessness and at the same time also be a consequence of it. Another crisis is the loss of a job followed by the lapse into unemployment. Racism, particularly against Blacks, has played a powerful role in bringing about and perpetuating homelessness.

How Many People Are Homeless?

Since the homeless population is transient, the actual number of homeless is uncertain. The number cited is usually based on those times when surveys are made by on-street interviews and counts at shelters, soup kitchens, and other such programs. It is estimated that 750,000 Americans are homeless on any given night and close to 2 million are homeless during the course of a year. There are countless people unaccounted for who manage to live in temporary locations such as subway caves, empty buildings, public areas, and the like.

Consequences

Homelessness often leads to stress, psychiatric disorders, and Substance Abuse: Alcohol abuse is the most prevalent health problem. Nearly two thirds of the homeless suffer from infectious or chronic diseases. Among the homeless are AIDS victims. In addition, the homeless typically lack adequate medical care or access to treatment. Medicaid and other welfare benefits are often unattainable to the homeless.

Children

Children are at greatest risk for the detrimental effects of homelessness, and they suffer the most physical, psychological, and emotional damage. Their physical development may be delayed, and children are susceptible to infectious and communicable diseases.

Among the homeless 3- to 5-year-olds, behavioral problems have been observed. Children older than age 5 frequently act out their anxieties. The foreboding danger for children is the inevitability that they are virtually trapped in poverty with no escape from homelessness. Thus poverty and homelessness may become a self-fulfilling prophecy passed on through the generations.

Bonds between the homeless parents and children weaken because parents are likely to assume a diminished role as disciplinarians and nurturers. Potential for child abuse is rife when the frustrations of homelessness exceed parental self-control.

Far too many homeless children skip school, fail and repeat grades, perform below the average, test poorly in reading and math, and are functionally illiterate.

Adolescents

Homeless adolescents are described as street kids, runaways, throwaways, and system youths who leave social service placements. Frequently, these adolescents come from dysfunctional families in which they are physically and sexually abused.

Health and Substance Abuse problems are common, as are sexual experiences, which make adolescents vulnerable to hepatitis and AIDS.

Lack of supportive and functional families is cited as the key factor associated with homeless adolescents. Large numbers of homeless youths are depressed and at risk for suicide.

Psychological Trauma

The psychological impact of homelessness can be as detrimental to one's self-esteem and well-being as the physical loss of housing. Homeless people may suffer from extraordinary stresses (e.g., psychological trauma resulting from loss of housing, living in a shelter, or victimization). A symptom of psychological trauma is social disaffiliation, breaking the bonds of attachment to significant others and to social institutions. Homelessness leads to distrust of others and isolation.

A second symptom is learned helplessness. Traumatized homeless individuals come to believe that they have no control over their lives and that they must depend on others to fulfill their basic needs. Among the homeless who suffer from traumatic victimization are battered women, some of whom report having been abused in childhood. In addition to social disaffiliation and learned helplessness, traumatized women also may display other dysfunctional symptoms, and many are abusive parents.

Solutions

Homelessness impinges on everyone in some way. When food and shelter are lacking, individuals cannot fulfill their need for self-actualization. Human resources that could be applied to improve the quality of their lives remain untapped.

In our society, because homelessness results from poverty, the first priorities for helping the homeless include building permanent affordable housing, providing income enhancement, and expanding health care.

The magnitude of the problem is so great that many be-

lieve only a federal effort to finance and administer such a project could eventually bring about its resolution. Failure to act eventually will be costly to the public and in terms of human suffering. Temporary overcrowded emergency shelters will become a permanent feature of the American landscape, and the homeless will continue to multiply at an uncontrollable and unprecedented rate at home and abroad.

HOMEOSTASIS

Complex organisms must maintain relatively stable internal environments to survive and move freely through the changing and often adverse conditions that surround them. *Homeostasis* is the name given to this constancy in 1926 by Walter B. Cannon, an American physiologist. Through his work on homeostasis, Cannon created a concept that is a milestone in the history of ideas. It was the culmination of an approach begun some six decades earlier with the work of Claude Bernard, the French physiologist who established the foundations of scientific physiology. Bernard concluded that organisms have evolved toward a greater independence from the changing environment by developing from the blood and bodily fluids an internal environment held stable by its own adjustments. Cannon demonstrated that the activities of homeostasis, often simple if viewed each in isolation, are nevertheless orchestrated by remarkably complex regulatory processes involving the organism across physiological systems and levels of functioning.

In 1925, Cannon described his findings as instances of the maintenance of steady states in open systems. In 1926 he named this steady condition *homeostasis* and offered a set of postulates regarding its nature. In 1929, he discussed the homeostatic regulatory mechanisms identified up to that point. The body, he asserted, was able through homeostatic reactions to maintain stability in the fluid matrix surrounding the body cells, thus controlling body temperature, blood pressure, and other aspects of the internal environment necessary for life. Regulated by the nervous system and endocrine glands, bodily reactions at all levels of complexity were involved in homeostasis, from the speed with which cell metabolism proceeded and produced heat in cold weather, to increases and decreases in the complex processes giving rise to hunger and thirst, with impact on behaviors affecting energy and water intake.

Cannon's concept of homeostasis emerged as a complex statement regarding the existence, nature, and principles of self-regulating systems. He emphasized that complex living beings are open systems made up of changing and unstable components subjected continually to disturbing conditions precisely because they are open to their surroundings in so many ways. While continuously tending toward change, living beings must maintain constancy with regard to the environment in order to preserve circumstances favorable to life. Adjustments within such systems must be continuous and less than perfect. Homeostasis therefore describes a state that is relatively, rather than absolutely, stable.

The concept of the open system challenged all conventional views regarding the appropriate unit of analysis of an entity. If the heart, lungs, kidneys, and blood, for example, are parts of a self-regulating system, then their actions or functions cannot be understood by studying each alone. Full understanding comes only from knowledge of how each acts with reference to the others. The concept of the open system also challenged all conventional views of causality, substituting complex reciprocal determination for any notion of simple serial or linear causality. Homeostasis therefore offered a new perspective both for viewing the behavior of systems of many sorts and for understanding people as members of open systems.

Homeostasis has served as a cornerstone for a number of subsequent developments involving a system perspective of control and causality. Hans Selye's work with stress and disease, and his discovery of the general adaptation syndrome, began with the insight that certain diseases and disorders might arise as the cost of the body's struggle to maintain homeostasis in the face of prolonged disruptive pressure. Selye's view of disease as derangement of homeostasis contributed to a view of health in which the role of medicine is to assist the homeostatic processes to return the organism to the constant state. Norbert Wiener's 1948 cybernetic theory attempted to formulate principles to account for self-regulation across biological and nonliving systems such as computers, a pursuit construed even more broadly in Ludwig von Bertalanffy's general system theory.

Homeostasis research continues to stimulate new perceptions, in recent decades by establishing that learning can play a central role in homeostatic regulation of even physiological systems, such as those involved in the increasing drug tolerance levels found in addictions. In a series of experiments starting in the 1970s, for example, Shepard Siegel showed that increased morphine tolerance in rats involves a learning process. A body of subsequent research supported the conclusion that the increasing levels of drug tolerance associated with repeated drug administrations involve learned homeostatic efforts to restore normal functioning in the presence of drugs that otherwise destabilize normal functioning. With repeated exposure to the drug, the organism learns to produce a pattern of offsetting physiological and/or behavioral responses that counteract the perturbing effects of the drug. In the 1990s, D. S. Ramsay and S. C. Woods demonstrated that, once learned, this pattern of homeostatic responses can even be elicited in anticipation of the drug. Overall, Cannon's sys-

tem concepts continue to play a central role in organizing our understanding of the nature of our interactions with our inner and outer environments.

HOMOSEXUALITY

Homosexuality refers to sexual behaviors, desires, attractions, and relationships among people of the same sex, as well as to the culture, identities, and communities associated with them. The term encompasses at least five phenomena that are often, although not always, related. First, it is used to describe any specific instance of sexual behavior with or attraction to a person of one's same sex. Both homosexual and heterosexual behaviors and attractions are common throughout human societies and across species. Second, it refers to ongoing patterns of attraction for sexual or romantic partners of one's own gender, which may or may not be expressed behaviorally.

A third aspect of homosexuality is psychological identity, that is, a sense of self defined in terms of one's enduring attractions to members of the same sex. Individuals who identify as homosexual typically refer to themselves as "gay," with most women preferring the term "lesbian." Some use "queer" as a self-descriptive term, thereby transforming a formerly pejorative label into a positive statement of identity. People follow multiple paths to arrive at an adult homosexual identity. Not everyone with homosexual attractions develops a gay or lesbian identity, and not all people who identify themselves as gay engage in homosexual acts.

A fourth component of homosexuality is involvement in same-sex relationships. Many gay and lesbian people are in a long-term intimate relationship and, like heterosexual pairings, those partnerships are characterized by diverse living arrangements, styles of communication, levels of commitment, patterns of intimacy, and methods of conflict resolution. Heterosexual and homosexual relationships do not differ in overall psychological adjustment or satisfaction. However, antigay stigma often denies same-sex partners the social support that heterosexual spouses typically receive, and even forces many same-sex couples to keep their relationship hidden from others.

Fifth, in the United States and many other societies, homosexuality involves a sense of community membership, similar to that experienced by ethnic, religious, and cultural minority groups. Empirical research indicates that gay men and lesbians in the United States tend to be better adjusted psychologically to the extent that they identify with and feel part of such a community.

The fact that the term homosexuality has multiple meanings highlights the difficulties of defining exactly who is gay. Moreover, many gay people do not disclose their sexual orientation publicly because they fear discrimination and harassment. Consequently, no accurate estimate exists for the proportions of the U.S. population that are homosexual, heterosexual, and bisexual. In North American and European studies during the 1980s and 1990s, roughly 1–10% of men and 1–6% percent of women (depending on the survey and the country) reported having had sexual relations with another person of their own sex since puberty.

Behavioral and Social Science Research on Homosexuality

The American mental health profession regarded homosexuality as an illness for much of the twentieth century. This classification reflected value assumptions and the viewpoints of particular schools of psychoanalysis rather than empirical data obtained scientifically from nonpatient samples. Its accuracy came into question when behavioral scientists began to systematically study the psychological functioning of homosexuals. Beginning with Evelyn Hooker's pioneering research in the 1950s, those studies consistently failed to find an inherent connection between homosexuality and pathology. In 1973, the weight of empirical data, coupled with changing social mores and the emergence of a politically active gay community in the United States, led the American Psychiatric Association to declare that homosexuality would no longer be considered an illness. Since then, the mental health professions have recognized that society's continuing prejudice against homosexuality is often a source of significant stress for gay men and women and sometimes leads to serious psychological distress and maladaptive behaviors. Consequently, many psychologists, psychiatrists, and other professionals are working to remove the stigma historically associated with homosexuality.

When homosexuality was regarded as an illness, its origin or cause was a topic of much speculation. More recently, researchers have recognized that the etiology of heterosexuality is equally puzzling, and scholarly inquiry now addresses the broad question of how sexual orientation develops in any given individual. A satisfactory answer to this question has not yet been found. It is possible that scientists will eventually identify multiple ways in which a person comes to be heterosexual, homosexual, or bisexual, with biological, psychological, and cultural factors all playing a role in this complex process.

Regardless of its origins, a heterosexual or homosexual orientation is experienced by most people in the United States and other Western industrialized societies as a deeply rooted and unchangeable part of themselves. Many adults report never having made a conscious choice about

their sexual orientation and always having felt sexual attractions and desires to people of a particular sex. When homosexuality was assumed to be a form of psychopathology, psychiatrists and psychologists often attempted to "cure" it; that is, they tried to change homosexual people into heterosexuals. Even today, some counselors and psychotherapists continue this practice. However, such treatments are widely rejected by mainstream therapists because they are usually ineffective, often harmful to the client, and ethically questionable. Instead, most mental health practitioners working with lesbian and gay clients try to assist them in developing positive feelings about their sexuality, establishing meaningful intimate relationships, and coping with societal stigma.

Scientific studies demonstrate that gay men and lesbians constitute a highly diverse group. Apart from their sexual orientation, they are no more homogeneous than the heterosexual population. Researchers have failed to find significant differences between homosexual and heterosexual people on a wide range of characteristics, including psychological adjustment, the capacity to form and maintain intimate relationships, the ability to be a good parent, the likelihood of victimizing children or adults, and the ability to function effectively in work groups and organizations.

Conclusion

Psychology today regards homosexuality as a different, rather than pathological, form of sexuality. Psychology also recognizes the considerable diversity that exists among gay men and lesbians, and increasingly seeks to address the problems they face as a result of the stigma historically associated with homosexuality in the United States.

HOPE: THE IMPERATIVE HUMAN MOTIVE

The frequency with which we use the word *hope* in our daily interactions reveals the extent to which it is woven into the fabric of our lives. Despite the pervasiveness of hope, however, its meaning may be elusive. Try thinking of a synonym for hope. This probably is more difficult than you had imagined. Given this ubiquitous yet vague nature of hope, we seek to elucidate a concise definition of hope, to provide a brief overview of a theory of hope that is being used in psychology, and to describe the role of this vital motive for adaptive human functioning.

Throughout history, hope has been viewed as a virtue or an emotion—or both. With the emergence of cognitive psychological theories in the 1960s, however, hope began to be seen as an important cognitive construct. In this regard, researchers explored how hope could relieve stress by allowing people to believe that things will get better. Beliefs that outcomes are controllable and that one can influence those outcomes bolster such hope.

Focusing on the antecedents of psychopathology and mental illness, theorists such as Aaron Beck, Lyn Abramson, and Lauren Alloy developed theories of hopelessness—the perception that negative outcomes cannot be avoided. Such hopelessness taps apathy, as well as a general lack of positive expectancies and enthusiasm toward the future.

In contrast to this focus on attempting to avoid negative outcomes, other theorists such as Erik Erikson and Ezra Stotland recognized the significance of hope for adaptive functioning. Erikson viewed hope as resulting from successful negotiation of the first stage of human development—moving from mistrust to trust in the world. Similarly, Stotland defined hope as reflected positive cognitive schemas, or internal belief structures, that predispose our expectations about how our goal-related behaviors will shape the future. Thus, hope involves our perceptions about the probability of goal attainment and the accompanying motivation to reach the goal.

Expanding on these goal-based conceptualizations, C. R. Snyder and his colleagues developed a theory and definition of hope that easily can be measured. In this contemporary theory of hope, the ability to clearly conceptualize goals is accompanied by two additional cognitive processes: the perceived ability to develop specific strategies for attaining the goal (called *pathways*), and the perception that one can muster the requisite motivation to use those chosen pathways (termed *agency*). As such, pathways and agency are both necessary, although neither alone is sufficient for goal attainment. For example, if an individual cannot identify pathways to a goal, no amount of agency will lead to the goal's attainment. Likewise, in the absence of a plan, goal-directed motivation is useless.

Hope as described here is learned over the course of childhood through interactions with a consistently responsive and supportive caregiver who serves as a role model and who acts as a hope-inducing coach. Such interactions teach the child to trust in the consistency of cause-and-effect relationships and to trust that others will be available to lend assistance in attaining personal goals. These high-hope children continue to view others as available and supportive into adulthood. Thus, other people can be viewed as sources of hope agency ("you can do it!") as well as resources for pathways by providing needed information. Over time, high-hope people view the world as consistent and safe and themselves as worthy of support. Hence, they characteristically focus on success and experience positive emotional states.

Although emotions are related to hope, they are not the primary ingredients of hopeful thinking. Goal-directed thoughts are at the core of hope. In hope theory, emotions follow cognitions as the individual pursues valued goals. As the individual initiates the goal pursuit along chosen path-

ways, which can be conceived of as a collection of incremental subgoals, the experience of success at each stage along the way produces positive emotional experiences. Conversely, lack of success at these subgoal stages leads to negative affect. Thus, emotions feed back and act as affective cues that, when interpreted cognitively, inform people of the correctness of their courses toward goals. Likewise, negative emotions lessen motivation and may lead to a reevaluation of previously chosen pathways.

Over time, hope becomes a traitlike disposition relating to an individual's overall perception that he or she has the ability to attain desired goals. Someone who has experienced minimal success in past goal pursuits may subsequently perceive little chance of successfully pursuing future goals. In this case, the individual quickly gives up when encountering impediments or does not expend the requisite energy to succeed. In contrast, reinforced by positive emotional feedback, higher-hope people develop a large number of goals and identify alternative pathways for reaching those goals in case the original pathways become blocked or fail to yield desired outcomes.

The perceived ability to develop effective strategies for reaching goals, accompanied by positive emotional reinforcement, leads high-hope people to choose challenging goals. Consequently, hope contributes to positive outcomes. In the area of education, for example, research shows that hope is positively related to perceived self-worth, scholastic competence, and social competence, along with higher grades among students from elementary school through the college years. In the area of mental health, hope is a common factor in successful psychotherapy, and it promotes greater psychological well-being, less anxiety, and fewer depressive symptoms.

Because of its adaptive significance, hope provides the basis for developing interventions to improve the quality of life for individuals and for society as a whole. Furthermore, people can be taught to become more hopeful by setting clear goals for their futures, making commitments, and staying the course until they have reached their objectives. Thus, hope is a crucial motive for coping, change, and positive growth.

HUMAN DEVELOPMENT

Life-span developmental psychology proposes that human development occurs from conception to death and that it involves the intricate interweaving of biological, sociocultural, and psychological processes (Baltes, 1987; Baltes, Lindenberger, & Staudinger, 1998). With regard to individual development, this theoretical approach focuses on (1) how single individuals change over time (intra-individual change); (2) differences between individuals during different developmental periods (interindividual variability); and (3) differences in individuals' patterns of change over time (interindividual variability in intra-individual change). Life-span developmentalists assume that human development can be conceptualized consistent with a series of principles and can be studied using research methodologies that capture the complexity of developmental processes.

Human development theorists have debated two issues concerning the continuity and discontinuity in developmental processes. In response to whether there are certain *age periods* (e.g., early childhood) that hold primacy in human development, or whether development occurs at all stages of the life span, the empirical literature supports the conclusion that humans have a capacity for change across the entire life span (Brim & Kagan, 1980) and that "no age period holds supremacy in regulating the nature of development" (Baltes, 1987, p. 613). The second issue, whether development proceeds in a smooth, linear, and *continuous manner* or whether development proceeds through a series of discontinuous stages, is resolved with the recognition that at all stages of the life span, both *continuous* (cumulative) and *discontinuous* (qualitatively different and innovative) processes are at work (Baltes, 1987; Lerner, 1984).

A core principle of human development is its *multidimensionality* and *multidirectionality.* Regardless of the developmental domain, multiple dimensions are required to capture the complexity of behavioral changes over time. The sequencing of changes, the conditions influencing continuity and change, the direction of changes (increasing or decreasing in complexity, frequency, or salience), and the pacing of changes tend to vary across dimensions within any domain. Only through the examination of multidirectional variations in the trajectories of change of multiple dimensions over time can the complexity of human development be elucidated.

The process of human development is not a simple movement toward higher efficiency, such as incremental growth. Rather, throughout life, development always consists of the joint occurrence of *gain* (growth) and *loss* (decline). In contrast to earlier views of human development that focused solely on processes that generated increasing capacity or complexity, life-span models of human development assert that in order to gain capacity in one dimension, loss must occur in another (Baltes, 1987). New adaptive capacities replace or subsume previously functional ones that have been lost. As reserve capacity and the range of plasticity decline in later life, older adults select more carefully the domains of functioning in which they try to maintain high efficacy and, when necessary, rely on compensatory mechanisms to adapt to the demands of the environment within those specialized domains (Baltes & Baltes, 1990).

Plasticity refers to the "processes by which one develops one's capacity to modify one's behavior to adjust to, or fit, the demands of a particular context" (Lerner, 1984, p. 10). This principle presumes the organism's capacity to influence the environment and itself in order to shape the course of its own development. Structural characteristics of the species both create the potential for, and set the constraints on, behavioral plasticity.

Two key propositions of the life-span perspective on human development are *contextual embeddedness* and *dynamic interaction* (Lerner, 1984). Contextual embeddedness refers to the idea that the key phenomena of human life exist at multiple levels (e.g., inner-biological, individual-psychological, social-sociological, cultural-historical, outer-physical/ecological) that influence each other in reciprocal ways. Thus, the task of human developmentalists is to describe and explain how different levels interact and influence each other and to optimize the parameters that affect these interactions and the resulting developmental trajectories (Baltes et al., 1998; Lerner, 1984).

Taken together, the basic principles of life-span development make *multidisciplinary inquiry* a necessity. Developmental changes in human behavior can only be explained by engaging in multiple levels of analysis of both internal and external contexts, leading to the inevitable necessity that development will only be understood when multiple disciplines work together to examine developmental processes.

Although theorists have argued that human development research requires observation over the "period of time during which the developmental phenomena of interest are thought to occur" (Schaie, 1983, p. 1), developmental research has mostly relied on cross-sectional comparisons of different age groups. Although valuable in informing researchers about the possible magnitude and the pattern of age differences in a certain behavior at a given point in time, cross-sectional studies are limited in providing information about developmental changes (Schaie, 1994). Longitudinal studies that track individuals over the course of their development permit (1) the direct identification of intra-individual change; (2) the identification of interindividual variability in intra-individual change; (3) the assessment of the interrelationships among different domains of intra-individual change; (4) the analysis of determinants or correlates of intra-individual change; and (5) the analysis of interindividual variability in the determinants or correlates of intra-individual change (Schaie, 1983). However, longitudinal designs share problems inherent in quasi-experimental designs (Campbell & Stanley, 1967) and confound time-of-measurement and aging effects that render estimates of age effects internally invalid (Schaie, 1983, 1994). *Sequential study designs* address many of these limitations (Schaie, 1994). Life-span developmental psychology has made great progress in the description, explanation, and optimization of human development across the whole life span. The use of longitudinal and sequential research designs has resulted in elaborate multivariate studies of behavioral development, showing that development occurs at all stages of the human life course from conception to death. In general, human development is characterized by processes of continuity and discontinuity, multidirectionality, gains and losses, and modifiability, and has as the ultimate goal the realization of a person's fullest potential.

HUMAN INTELLIGENCE

The Definition of Intelligence

Intelligence, according to *Webster's New World College Dictionary* (3rd ed.), is "the ability to learn or understand from experience, ability to acquire and retain knowledge; mental ability" (Neufeldt, 1997, p. 702). Such a definition cap-

tures many facets of the nature of intelligence, but not necessarily those believed to be key by experts.

Two symposia have sought to ascertain the key features of intelligence according to experts in the field ("Intelligence and its Measurement," 1921; Sternberg & Detterman, 1986). Critical elements of the definition of intelligence, according to experts, are (1) adaptation in order to meet the demands of the environment effectively, (2) elementary processes of perception and attention, (3) higher-level processes of abstract reasoning, mental representation, problem solving, decision making, (4) ability to learn, and (5) effective behavior in response to problem situations. Some experts, however, have been content to define intelligence operationally, simply as the intelligence quotient, or IQ (Boring, 1923). These definitions rely on tests such as those originated by Binet and Simon (1916) to measure judgmental abilities or of Wechsler (1939) to measure verbal and performance abilities.

Laypeople also can be asked to define intelligence, and it turns out that their definitions differ from expert definitions in placing somewhat greater emphasis on social-competence skills. In one study, for example, laypeople defined intelligence in terms of three broad classes of skills: (1) practical problem solving, (2) verbal ability, and (3) social competence (Sternberg, Conway, Ketron, & Bernstein, 1981). Definitions can vary somewhat across occupations (Sternberg, 1985).

Heritability and Modifiability

Whatever human intelligence may be, that aspect of it measured as IQ is both partially heritable—with a heritability coefficient estimated at about .5 (albeit slightly lower in childhood and somewhat higher in adulthood)—and modifiable in at least some degree (Sternberg & Grigorenko, 1997). Indeed, intelligence as measured by IQ tests has been rising steadily through most of the century (Neisser, 1998).

Theories of Intelligence

Another approach to understanding intelligence is through a more elaborated theory. A theory, in contrast to a definition, must provide an explanatory framework and be testable. Theories have been of several different kinds.

Psychometric Theories

The best-known theories are probably psychometric ones. Among these theories, the earliest major one is that of Spearman (1927), who proposed that intelligence comprises a general factor (*g*) of intelligence common to all intellectual tasks, as well as specific factors (*s*), each of which is unique to a given test of intelligence. His proposal was based on his finding of a "positive manifold" among intelligence tests: All tests seemed to be positively intercorrelated, suggesting the existence of a general factor. Spearman's theory still has many proponents today (e.g., Jensen, 1998). Thurstone (1938) disagreed with Spearman, arguing that the general factor was an artifact of the way Spearman analyzed his data. Thurstone suggested that seven primary mental abilities underlie intelligence: verbal comprehension, verbal fluency, number, spatial visualization, inductive reasoning, memory, and perceptual speed. More modern theorists, such as Cattell (1971) and Carroll (1993), have attempted to integrate these two kinds of views, suggesting that intelligence is best understood hierarchically, with a general factor at the top of the hierarchy and narrower factors under it. Cattell proposed two such factors: fluid intelligence, which is involved in reasoning with novel kinds of stimuli, and crystallized intelligence, or stored knowledge base.

Systems Theories

Some theories of intelligence have viewed intelligence as a system. By far the best-known theory of this kind is that of Piaget (1972), according to which intelligence involves an equilibration between two processes: assimilation of new information to fit existing cognitive structures, and accommodation of existing cognitive structures to incorporate information that does not fit into preexisting cognitive structures. Sternberg (1997) has proposed that intelligence comprises three aspects: analytical abilities (used to analyze, evaluate, and critique), creative abilities (used to create, discover, and invent), and practical abilities (used to apply, implement, and use). Gardner (1999) has suggested instead that there are eight multiple intelligences—linguistic, logical-mathematical, spatial, musical, bodily-kinesthetic, naturalist, intrapersonal, and interpersonal—and perhaps existential intelligence as well.

HUMAN LOCOMOTION

In the eighteenth century, the investigation of movement was based on the premise that upright stance and gait and also differentiation of hand movements represented a basic requirement for human cultural development. This necessitates that the nervous system must function to automatically balance the body's center of mass over the feet during all motor activities. In other words, every movement must begin and end with a postural adjustment. Nevertheless, basic neuronal mechanisms underlying quadrupedal locomotion remain preserved during human gait.

Analysis of human gait first became possible toward the end of the nineteenth century with the development of photographic recordings of running movements. Later, the technique for recording electrophysiological responses during locomotion was developed and was first demonstrated in cats.

The relative significance of reflexes on central rhythms and programming in locomotion has been addressed. The *central mechanisms* involved in locomotion are reflected in a reciprocal mode of leg muscle activation and a di- or triphasic pattern of antagonistic leg muscle activity following displacement of the feet that is thought to be programmed in its basic structure. This electromyographic (EMG) pattern is assumed be evoked by a multisensory afferent input and generated by spinal interneuronal circuits that are closely connected with spinal locomotor centers. The extent to which the timing of the pattern can be modified by afferent input has not yet been fully explored. A basic requirement of bipedal locomotion is that both legs act in a cooperative manner; each limb affects the strength of muscle activation and the time-space behavior of the other. There exists some evidence that this interlimb coordination is mediated by spinal interneuronal circuits, which are themselves under supraspinal (e.g., cerebral and cerebellar) control.

In regard to the *reflex mechanisms,* short latency stretch reflexes in leg extensor muscles are profoundly modulated during gait mainly by presynaptic inhibition group IA input and less by fusimotor influences. During large translational perturbations a significant contribution of this reflex has not yet been demonstrated. However, they may be involved in the compensation of the small ground irregularities at distinct phases of gait. Compensation for larger displacements during gait is provided by polysynaptic spinal reflexes. This includes an activation of synergistic muscle groups of both legs. These EMG responses are thought to be mediated predominantly by peripheral information from group II (and probably III) afferents, converging with different peripheral and supraspinal inputs onto common interneurons on a spinal level. These reflexes modulate the basic motor pattern of spinal interneuronal circuits underlying the respective motor task.

During recent years, increasing evidence has come up for the crucial importance of load receptor input in the control of bipedal stance and gait in quadrupeds and bipeds. Yet we are still at the beginning of an understanding of its nature and its interaction with other afferent inputs and control mechanisms. Vestibular and visual functions are mainly context dependent and are essential when afferent input from other sources is reduced.

One of the first symptoms of a lesion within the central motor system represents *movement disorder,* which is most characteristic during locomotion in patients with spasticity, cerebellar lesions, or Parkinson's disease. The *clinical* examination reveals typical changes in tendon tap reflexes and muscle tone typical for one of the movement disorders. However, today we know that there exists only a weak relationship between the physical signs obtained during the clinical examination in a passive motor condition and the impaired neuronal mechanisms in operation during an active movement. By the recording and analysis of electrophysiological and biomechanical parameters during a functional movement such as locomotion, the significance of, for example, impaired reflex behavior or pathophysiology of muscle tone and its contribution to the movement disorder can reliably be assessed. Consequently, an adequate treatment should not be restricted to the cosmetic therapy and correction of an isolated clinical parameter but should be based on the pathophysiology and significance of the mechanisms underlying the disorder of functional movement that impairs the patient.

HUMAN RELATIONS TRAINING

Once heralded by Carl Rogers as "the most important social invention of the twentieth century," human relations training has failed to meet the promise inherent in that statement. Human relations training (HRT), also known as group-dynamics training, encounter groups, sensitivity training, or T-groups (for training), is rarely the focus of either the theory or practice of psychology in the first decade of the twenty-first century. With the possible exception of those committed to a humanistic psychology perspective, HRT has become simply one approach to increasing management and work-group effectiveness.

The process of HRT typically involved a small group of persons, usually 12–15 in number, who would meet together over a specified period of time with the goal of increasing their own self-awareness, their understanding of others, and their knowledge of and skill in small-group dynamics. With the support of a trained facilitator, these process-oriented groups would engage in a variety of discussions, activities, and exercises that would allow participants to both reveal themselves as persons and receive feedback on the reactions of the other members of the group about how these revelations were experienced. As each member of the group provided such feedback, they would learn how congruent their reactions were with those of the others and thus learn more about how effective they were as observers. The key ingredient to promoting changes through HRT was the feedback process in which these various observations and reactions were shared. The facilitator or trainer would explain, model, and monitor the feedback to ensure that all such feedback was behaviorally based, nonjudgmental, and offered in a helpful context. Through this feedback process, participants would learn more about themselves, especially about the impact of their behavior on others. Such training programs typically last from 2 to 5 days.

A useful model for understanding how HRT functions to increase self-awareness is the Johari Window (Luft, 1961), which is presented in Figure 1. In the Johari Window, Quadrant I, the open or public quadrant, represents the behaviors that are known both to the self and to others. Quadrant II, the blind quadrant, represents behaviors known to others but not to the self, while Quadrant III, the hidden or secret quadrant, refers to behaviors known to the self but not to others. The unknown quadrant, Quadrant IV, represents behaviors known to neither the self nor others. Perhaps the most important goal of HRT is to increase the size of the public area (Quadrant I) and to reduce the size of the blind and hidden areas. This increase in the public area is seen as an important way to increase interpersonal competence and effectiveness in human relationships.

One can enlarge one's public area through self-disclosure, thereby reducing the secret area, and through receiving feedback about one's behavior, especially its impact upon others, which reduces the blind area. HRT training is typically designed to elicit a wide range of self-disclosing behaviors that are not typically exhibited by the individual, which permit others to have a broader knowledge of the person. The leader or trainer then encourages the person to request feedback about how those behaviors affect the others in the group. Thus self-disclosure and feedback lead to an increase in the open or public area and, presumably, to increased interpersonal competence. The reduction in the size of both the blind and hidden areas should then reduce the size of the unknown area. All of this is carried out in a laboratory environment that encourages behavioral experimentation and where trust, nondefensiveness, and interpersonal warmth should predominate.

In a similar fashion, the participants in HRT can be helped by the facilitator to observe various group processes as they occur in the course of the program. The various stages of group development can be noted, the various group roles that participants play can be examined, the group's decision-making processes can be reviewed, and so on. Thus HRT is seen as a vehicle for learning both about the self and about group dynamics. The role of the facilitator, also known as the trainer or group leader, in HRT is to

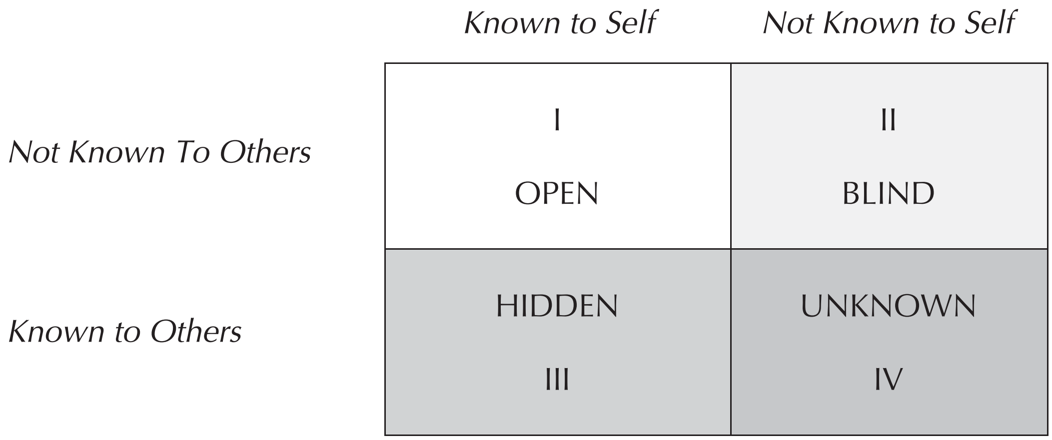

Figure 1. The Johari Window (after J. Luft, 1961).

assist the group in setting the structure and norms for the early work of the group and in processing learning, on both individual and group levels.

There are any number of reasons for the loss of interest in HRT on the part of psychologists. The lack of any standardization in HRT, the enormous variations in the training and skills of HRT facilitators, and the reports of serious emotional breakdowns in HRT were all contributors, as was the decline in interest by social psychologists in small-group research (Goodstein & Dovico, 1979). But probably the most important factor was the lack of empirical evidence on the long-term effectiveness of HRT.

The research on the effectiveness of HRT (Campbell & Dunnette, 1968; Dunnette & Campbell, 1968) suggests that although such training does produce positive changes in behavior, there is little evidence that the effects of training transfer to the participants' home environments. One exception to these findings is the report by Hand, Richards, and Slocum (1973), who followed a group of managers for 18 months after they participated in HRT and found that, in contrast to a matched control group, the members of the trained group had more self-awareness and were more sensitive to others, and that their subordinates were also aware of these changes. It is interesting to note that these performance ratings increased only for those trained participants who worked in consultative environments, but not for those in autocratic environments. Yet, overall, the support for the long-term impact of HRT on interpersonal competence is limited, which undoubtedly was an important factor in its demise as an important psychological activity.

Perhaps the most important legacy of HRT, however, is its focus on the importance of feedback in modifying human behavior. This focus may help account for the current interest by psychologists and others in using 360-degree feedback and in managerial coaching based upon that feedback. In 360-degree feedback, an individual is rated by superiors, peers, and subordinates, using a standardized, reliable behavioral rating instrument. These ratings are then compared with the individual's self-rating, and any differences become the basis for coaching to reduce these differences—a process similar in intent to HRT but one based upon a data set with which psychologists are more comfortable.

HUNGER

Feelings and Behaviors

The subjective states related to eating are familiar. Hunger, for example, increases during fasts, whether these are voluntary intermeal intervals or externally enforced fasts. Hunger is also elicited by conditioned stimuli, such as Pavlov's legendary bell. The complementary states of satiety are equally familiar. Although the psychology of subjective states of hunger and satiety has been studied for many years, newer methods, including brain imaging, are now making them accessible to neuroscientific analysis.

The functional behavioral unit related to hunger and satiety is the meal. Patterns of spontaneous meal sizes and intermeal intervals are biologically organized, as is evident from the characteristic spontaneous eating patterns displayed by humans and other animals and from the predictable changes in meal patterns in response to various physiological and environmental variables. There are also more elementary biological units of eating behavior than meals. For example, neural networks in the brain stem produce patterns of licks, bites, chews, and swallows of food, and these also vary predictably in many states in ways that modify meal size. These units of eating are attracting increasing attention from neuroscientists who are analyzing how the brain produces eating behavior.

Food Selection and Meal Initiation

Food selection and meal initiation are controlled mainly by conditioned olfactory, visual, temporal, cognitive, and social stimuli. These are usually highly individuated, especially in humans. Two physiological signals are also known to be sufficient for normal meal initiation. First, small, brief, transient declines in blood glucose supply signal hunger. These declines are not hypoglycemia (i.e., decreases in blood glucose that reduce cellular glucose supply), which rarely occurs spontaneously. Second, certain changes in liver metabolism that occur between meals, such as changes in fatty acid oxidation, are sufficient to initiate eating. Gastric contractions are not signals for meal initiation; the referral of "hunger pangs" to the stomach seems an epiphenomenon.

Meal Size

Controls of the maintenance of eating and of the termination of eating determine meal size. Taste, especially sweet taste, is the only known unconditioned stimulus that affects eating once it has begun. Odors are crucial for flavor preferences, but their contribution is conditioned.

Feedback signals from the gastrointestinal tract provide unconditioned controls of meal termination. Most important are stomach volume, which is detected by mechanoreceptors in the gastric muscles, and small intestinal nutrient content, which is detected by chemoreceptors in the intestinal mucosal. Feedback information is encoded in the periphery as neural impulses in the vagus or splanchnic nerves or in the concentration of gut peptide hormones such as cholecystokinin (CCK).

Other feedbacks unrelated to the ongoing meal also control meal size. Most interesting are two hormones whose average blood levels are correlated with body fat content, insulin and leptin. The control of meal size and food intake by body fat can be dramatic or weak, depending, for example, on genetic variation, on the availability, palatability, variety, and energy density of food, and, probably, on conditioning.

Learning

Except the unconditioned effects of taste, all food identification, selection, and preference is learned. Little is known, however, about the complex social and cultural conditioning that so dramatically influences human appetite, producing, for example, the paradoxical preference for capsaicin (chili). Food's rewarding, satiating, metabolic, and toxic effects all support learning. A neutral flavor associated with a satiating food can simultaneously condition preference, so that flavor is preferred, and satiety, so less of foods of that flavor are eaten. Conditioned aversions linking tastes with certain forms of gastrointestinal illness are a dramatic example of a special biological preparedness: A single pairing of taste and illness suffices, the taste-illness interval can be hours, and the learning is very resistant to extinction.

Brain Mechanisms

Neuropharmacological methods, including the measurement of neurochemicals at their site of action in awake, behaving animals, link many specific neurochemical systems in the brain to hunger. Dopamine and endogenous opioids are neurotransmitters crucial for food reward (i.e., for the maintenance of eating during meals, the production of pleasure, and the reinforcement of learning about food). Neuropeptide Y (NPY), norepinephrine (NE), and agouti-related peptide also increase eating, apparently by increasing hunger rather than affecting reward. The most researched neurotransmitter that inhibits eating is serotonin (5-hydroxytryptamine, 5HT), which is important in food reward, CCK's satiating action, and conditioned preferences.

The outlines of the neural networks in the brain underlying eating have begun to take shape. Unconditioned controls of meal size apparently can act in the brain stem to inhibit eating. In the forebrain, the hypothalamus is a crucial node for both conditioned and unconditioned controls of meal initiation and meal size. Reward certainly involves other basal forebrain areas, including the nucleus accumbens and the amygdala. More complex controls involve increasingly wide areas of the forebrain.

Eating Disorders

Both subjective and behavioral aspects of meals are disturbed in eating disorders. The behavioral neuroscience of eating has begun to contribute to understanding these problems. For example, patients with Bulimia Nervosa eat larger than normal meals under laboratory conditions; ingested food is less satiating than normal for these patients, and the decreased satiety is related to decreased CCK secretion.

HYPERACTIVITY

The term *hyperactivity* refers to both a symptom associated with a variety of medical and behavioral disorders and a common psychopathological syndrome. A range of related terms are often treated interchangeably, including *overactivity, hyperkinesis, minimal brain dysfunction, attention-deficit disorder,* and *Attention-Deficit/Hyperactivity Disorder.* This discussion will address hyperactivity as a descriptor, symptom, and syndrome, emphasizing the disorder currently called Attention-Deficit/Hyperactivity Disorder.

Descriptor

Activity level is an important developmental and temperamental dimension, representing an individual difference among all living beings. Developmental change is expected, as captured in the contrast between a frisky young puppy and a sedentary old dog. Thus, there is a range of behavior considered to be within normal limits. Exceeding these limits in either statistical or clinical terms can be called *overactivity.* Hyperactivity is a continuous form of movement such as squirming, fidgeting, or foot tapping, rather than discrete or episodic movement such as a spasm or a tic.

Overall activity level is one category of temperament: constitutionally based qualities of responsiveness that are evident and relatively stable throughout life. Hyperactivity, as a statistical or clinical extreme, has particular implications for problems in development and adaptation, which can contribute to secondary difficulties for the individual.

Symptom

A common, often primary, symptom, hyperactivity is observed in a variety of medical and behavioral disorders, including bipolar disorder, Schizophrenia, autism, developmental disabilities, metabolic disorders, endocrine disorders, toxic exposure (e.g., lead poisoning), and other neurological conditions (brain tumor, encephalitis, Parkinson's disease, etc.). Hyperactivity is not in itself a cause for concern. Instead, it is a nonspecific symptom whose significance depends on demographic and situational factors and the presence of other physiological characteristics or behavioral symptoms.

Syndrome

Despite the heterogeneity of conditions that include motor excess, there appears to be a set of covarying factors resulting in the identification of a hyperactivity syndrome or disorder. Hyperactivity does not constitute a syndrome in the technical sense of the word, because the particular pattern of symptoms or characteristics does not form a unitary cluster, nor is there adequate evidence of common etiology, both sine qua non of a true syndrome. However, the disorder most closely associated with hyperactivity is Attention-Deficit/Hyperactivity Disorder (ADHD; American Psychiatric Association, 1994). The core symptoms are hyperactivity, distractibility, and impulsivity.

Russell Barkley (1997a, 1997b, 1998) has summarized the research and developed a cohesive theory to explain ADHD and the disability it creates. As a developmental disorder, ADHD is present from birth, and symptoms manifest at a young age (before age 7). Symptoms are persistent rather than episodic and are present across situations. However, hyperactivity may be more obvious in settings where quiet, calm behavior is required and may go virtually unnoticed in unstructured settings where active behavior is allowed or encouraged, which accounts for the difference in a child's presentation in the classroom, on the playground, and at home.

Prevalence estimates range from 3 to 7%, with about 3 times more males than females affected. ADHD was conceptualized as a childhood disorder that one outgrew until longitudinal research showed that although some manifestations of the disorder become less problematic when formal education is completed, the overall pattern persists in at least 30–50% of the affected population. In addition to the primary symptoms, individuals with ADHD are at increased risk for poor academic progress, school difficulties, and poor interpersonal relationships. Increased rates of anxiety and depression, more aggressive and delinquent behavior, and increased rates of Substance Abuse also have been documented. Furthermore, adults with ADHD may have vocational difficulties, increased risk for motor vehicle accidents, and greater marital instability.

Specific etiology of ADHD remains unknown, although professional consensus leans toward biological explanations. Genetic perspectives are supported by the increased incidence of the disorder in relatives of those with ADHD and the overrepresentation of males, although intrafamilial variability does not rule out psychological or behavioral transmission. Organic explanations are supported by observations of similar behavior in individuals with traumatic head injuries, and the prevalence of hyperactivity in some metabolic disorders, suggesting that an acquired illness or injury may contribute to the condition.

Environmental factors associated with ADHD symp-

toms include toxins such as lead and exposure to radiation and specific medications. Although psychological hypotheses such as particular child-rearing patterns or learning patterns are less well accepted than other theories, these factors affect the course and outcome of the disorder.

Recently, Barkley and others have turned their attention to so-called executive functioning as the core deficit that causes ADHD. Barkley suggests that developmentally, certain types of self-regulation, including regulation of motor behavior and sustained attention, ought to emerge with age. These skills do not adequately develop in people with ADHD. Neuroimaging findings, neuropsychological tests, and laboratory tasks appear to provide converging evidence for this perspective, which identifies behavioral inhibition as the key deficit. However, given the range of factors that may contribute to ADHD, and the high prevalence of the disorder, it is likely that the actual etiology is multifactorial. Furthermore, if the notion of multiple syndromes is borne out, multiple etiologies are likely to be revealed.

Consistent with the variation in etiological hypotheses, assessment and treatment of the disorder is wide-ranging and crosses disciplinary lines with educators, physicians, and mental health providers all claiming ownership of the disorder. Neurodevelopmental, psychological, psychoeducational, and neuropsychological evaluations all are used to identify the disorder. Several valid and reliable parent and teacher rating scales have been developed for identification of ADHD. Many children are identified by their teachers or pediatricians in the absence of a comprehensive assessment, and there are no data comparing the accuracy of each type of diagnosis because there is no definitive test that proves the presence of this disorder. Recent attention has turned toward neuropsychological assessment tools, which may provide greater sensitivity and specificity; however, none of these has sufficient reliability or validity to be the "gold standard" for diagnosis. Consequently, comprehensive multidisciplinary assessment, incorporating parent and teacher reports, cognitive and behavioral assessment, and norm-based rating scales, is particularly desirable in diagnosing ADHD.

Treatment with stimulant medications such as methylphenidate or dextroamphetamine is the most common and most effective, yet controversial, treatment for ADHD. However, it is generally recognized that medication alone is insufficient to address either the primary disorder or its disabling effects. Therefore a variety of cognitive, behavioral, and psychoeducational interventions are necessary adjuncts to medication.

HYPERTENSION

Hypertension, a disease affecting the cardiovascular system and commonly known as high blood pressure, is a major health problem. It is characterized by chronic elevation of diastolic and, typically, systolic blood pressure without demonstrable pathology of either the blood vessels or the heart. Hypertension is a primary cause of adult sickness, disability, and death in the United States, afflicting approximately 50 million persons. Additionally, it is one of the most important risk factors in the promotion of atherosclerotic diseases, kidney failure, congestive heart failure, coronary heart disease, myocardial infarction (heart attack), and cerebrovascular accident (stroke).

Blood pressure occurs on a continuum, with no clear division between normal and elevated pressure. Further, the blood pressure values of concern to a practitioner vary as a function of a patient's history, age, sex, and environment. In general, however, blood pressure is regarded as high when the systolic pressure at rest consistently provides a measurement of 140 mm Hg (millimeters of mercury) or more, and the diastolic pressure is 90 mm Hg or more. Depending upon a variety of factors, a diagnosis of hypertension may or may not be applied when consistent readings above 140/90 (reported as one-forty over ninety) are obtained. Nevertheless, consistent readings above this level do warrant monitoring and perhaps remediation.

If remediation is selected, the treatment strategy depends upon the etiology of the malady. *Primary* or *essential hypertension* refers to an instance in which the cause is unknown, whereas *secondary hypertension* is the result of an identifiable antecedent, such as malfunction of particular endocrine organs, coarctation of the aorta, pregnancy, or oral contraceptive medication. Although secondary hypertension may be ameliorated via surgery or chemotherapy, this category accounts for a relatively small percentage of the cases.

In contrast to the low incidence of secondary hypertension, in about 80% of the patients evidencing hypertension there is no clear cause for the disease. Even though this type of hypertension is of unspecified etiology, it has been recognized for a long time that emotional factors, stress, and a fast-paced lifestyle have an elevating effect on blood

pressure. Within this context, much research has been directed toward establishing effective behavioral treatments that may be employed alone or in conjunction with a variety of pharmacological regimens. These behavioral treatments include progressive muscle relaxation, meditation, yoga exercises, autogenic training, biofeedback-assisted relaxation, blood pressure biofeedback, contingency managed aerobics and diet, as well as strategies combining two or more of these programs. In addition, when pharmacological intervention is necessary, a variety of classes of antihypertensions are available. These include B-adrenergic receptor antagonists, calcium channel blockers, diuretics, angiotensin-converting enzyme (ACE) inhibitors, and others. Treatment may involve one agent or a combination of these antihypertensive agents to attain normal blood pressure, or, at least, lower blood pressure to a more acceptable level.

HYPNOSIS

Hypnosis occurs within the context of a special hypnotist-subject relationship, during which suggestions of distortions of cognition, perception, memory, and affect can be responded to by some individuals who are able to control (voluntarily) their levels of consciousness. Hypnosis appears to be characterized by the dissociative subject's ability to temporarily accept as reality suggested distortions of perception, cognition, and affect.

Brief History of Hypnosis

The history of hypnosis begins with Franz Anton Mesmer (1734–1815). His patients gathered around the *baquet*—a tub of water filled with iron filings, with protruding rods held by the patients. The gathered ill became hypnotized, evinced by the ensuing *crisis* or hysterical seizure. A Royal Commission headed by Benjamin Franklin in Paris in 1784 led to the rejection of Mesmer's *animal magnetism.* The alleged therapeutic cures were dismissed as due to mere imagination.

James Braid (1852) introduced the term *hypnosis,* from the Greek *hypnos* (to sleep). Jean-Martin Charcot (1882) considered hypnosis a manifestation of hysteria, in women. Charcot influenced the development of dissociation theorizing by Janet and Prince, and also influenced Freud's observations of the hypnotic abreaction and his development of the concept of unconscious motivation. Freud later gave up hypnosis because, he stated, he could not hypnotize everybody. He did not understand that hypnosis was a characteristic of the individual rather than something done by a hypnotist/therapist. Hippolythe Bernheim (1886) saw hypnosis as "suggestibility"—a view championed by the first major research program in hypnosis, conducted by Clark Hull (1933). Modern counterparts of each of these developments persist.

Characteristics of Hypnosis

A number of standardized scales have been developed that have made it possible to measure hypnosis with high reliability and validity. The scales are based on objective behavioral ratings of responses to subjective suggestions graded in difficulty. Hypnotic responsiveness is unlikely to change over time.

The methodological sophistication of contemporary hypnosis research contributes to general psychological theory, including the evaluation of subjective experience, verbal reports, limits of performance, attention and consciousness, factors involved in the social psychology of the psychological experiment, pain, and clinical practice. Three illustrative areas can be summarized.

Trance Logic

Trance logic is the ability to tolerate logical incongruities. It is not particularly troublesome for the hypnotized person to regress to, for example, 7 years of age. At one level the hypnotized person knows reality exists, but at another level it can be suspended in an effortless absorption in a fantasy world. However, his or her recollection of past experiences may have been contaminated by the contextual aspects of memory. The hypnotized subject's regression may not accurately reproduce childhood experiences. Although the distorted and confabulated material may be important therapeutically, there is a disturbing tendency for hypnosis to be used in forensic applications based on the faulty premise of accurate recall. Hypnotized subjects can lie or confabulate under hypnosis just as easily as in the waking state.

Pain Control

Hypnosis can play an important role in pain control. Hypnotic analgesia involves two distinct processes: (1) Hypnosis can directly reduce pain at a sensory, physiological, or primary level; and (2) expectational or placebolike effects can reduce pain because of the special context in which hypnosis is induced. Thus, there is only a modest correlation

between the capacity for hypnosis and the capacity for pain control (and any other therapeutic intervention). This correlation is kept low by the impact of the nonspecific or placebolike factors brought into play in patients who are psychologically ready to give up their symptoms if an intervention is appropriately legitimized.

The profoundly analgesic subject can still report the objective pain stimulus conditions when the hypnotist addresses another part of the hypnotized subject's awareness (Hilgard's "hidden observer"). People operate on multiple cognitive levels (dissociation).

Characteristics of the Hypnotizable Person

The hypnotized subject seems tuned to multiple cognitive pathways and is easily able to distort reality while remaining aware of its existence at other levels of awareness. The hypnotizable person is not gullible, compliant, hysterical, weak-willed, passive, prone to placebo response, or subject to the control of the dominant hypnotist. Instead, he or she has the capacity to become absorbed in ongoing experiences (e.g., becoming lost in fantasy, or identifying with the emotions of a character in a play or movie). He or she reports imaginary playmates as a youngster. The hypnotizable subject may turn up late for experimental appointments—a puzzling finding for those who see hypnosis as role-playing performed to please the hypnotist.

Cognitive flexibility is the hallmark of the hypnotizable person. The hypnotizable person naps and falls asleep quickly at night, and has other characteristics that cluster together to define a dimension involving the "control of consciousness," or a basic individual difference in cognitive flexibility. This flexibility dimension explains why hypnotizability is a significant prognostic index of recovery from psychiatric illness and of the ability to give up symptoms.

Clinical Hypnosis

Professional Training in Clinical Hypnosis

Hypnosis is a technique, not a treatment. Its use must be integrated into the specialized skills of the professional in his or her area of competence. It is the skills of the professional therapist—knowing what to treat, when not to treat, possible side effects and complications—that define safety and efficacy when using the technique.

Training opportunities are available in many universities and medical schools. Two national hypnosis societies offer annual workshops limited to physicians, dentists, psychologists, nurses, and psychiatric social workers: the American Society of Clinical Hypnosis and the Society for Clinical and Experimental Hypnosis. Both societies publish a journal on hypnosis. The International Society of Hypnosis provides a forum for professional colleagues throughout the world.

Clinical Applications

Hypnosis is used to treat many medical, psychological, and behavioral problems. Claims of dramatic clinical results have not usually been well documented. Hypnosis can control pain in cancer and burn patients. It can modify chemotherapy-induced vomiting and nausea and ease discomfort of invasive procedures (e.g., debridement, bone marrow procedures) even with those of moderate hypnotizability. Hypnosis is especially useful in habit control where, for whatever reason, the patient is ready to give up a symptom and needs legitimization and a dramatic intervention to justify change. Hypnosis can establish whether patients have the resources to facilitate mind-body, self-control, and cognitive mastery over their symptoms. Hypnosis helps facilitate relaxation, allow ego strengthening, control anger and other negative emotions, uncover affect with age regression, develop imagery strategies, and facilitate symptom relief.

Summary

A comprehensive psychology of consciousness is probably needed to understand hypnosis. Hypnotic phenomena can provide paradigms for understanding important aspects of the psychopathology of everyday life. Some individuals can experience hypnosis and control different states of consciousness with flexibility.

HYPNOSIS AS A PSYCHOTHERAPEUTIC TECHNIQUE

Hypnosis is a procedure in which the use of suggestions presented by the therapist or researcher (or self, in the case of self-hypnosis) allows the hypnotized individual to experience changes in sensations, perceptions, thoughts, or behaviors. Hypnosis capitalizes upon an innate cognitive capacity that probably involves imaginative ability, the capacity to concentrate, and an effortless receptivity.

Typically, an induction procedure is used to establish the context in which hypnotic suggestions are presented. Although hypnotic inductions vary, most involve suggestions for relaxation, calmness, and a sense of well-being. On the other hand, active-alert inductions that involve physical activity have also been shown to be effective in establishing responsiveness to suggestion.

The ability to respond to hypnotic suggestions is a stable personality trait that varies little over time or situations. This trait of hypnotic responsiveness is normally distributed with the largest number of individuals able to experience some but not all types of hypnotic suggestions. Hypnotic responsiveness peaks at about 9 to 11 years of age, with a mild decrement taking place in later years. A highly responsive subject will become hypnotized under a host of experimental conditions and therapeutic settings. A low hypnotizable person will not, despite his or her sincere efforts. This trait of hypnotic responsiveness appears to be unrelated to other traits such as trust, interrogative suggestibility, and gullibility. Evidence exists that some highly dissociative individuals are also highly responsive to hypnosis, but for the general population, dissociativity and hypnotic responsiveness are minimally related, if at all.

Even highly hypnotizable subjects remain in control of their behavior when hypnotized and typically continue to be aware of self and surroundings. On the other hand, a major component of the experience of hypnosis is a sense of involuntariness. Kenneth Bowers best described this paradox when he stated, "hypnotic responses can be purposeful without being enacted on purpose." Hypnosis can be thought of as an invitation to experience suggested alterations, which the subject can then either accept or reject. Although amnesia can occur during hypnosis, for the most part this occurs only when explicit suggestions for amnesia are given, and the amnesia is reversible.

Contrary to some popular depictions, hypnosis is not a panacea for recovering forgotten memories. Research indicates that memories recalled under hypnosis may or may not be accurate. Further, difficulty distinguishing true memory from suggested memory arises as a result of increased confidence in memories that can occur under hypnosis. Hypnosis appears to diminish the ability to discriminate between fantasy and reality, and of course it involves enhanced responsiveness to suggestions. Similarly, hypnotic age regression does not enable subjects to return to an earlier point in their life. Observable alterations in behavior or speech following hypnotic age regression are no more childlike than those observed among adults role-playing as children.

Hypnosis is not a form of therapy per se but rather a procedure that can be used within the context of therapy or as an adjunct to medical treatment. Hypnosis is effective for some individuals and for some problems. Thus, hypnosis should be used only by a clinician or researcher who is familiar with the applications and limitations of hypnosis as well as being trained in the area for which hypnosis is being used.

It is well established that hypnosis can be a very effective tool for minimizing both acute and chronic pain for some individuals, and this effect exceeds that of placebo. In 1996, a National Institute of Health Technology Assessment Panel Report found hypnosis to be a viable and effective intervention for alleviating pain with cancer and with other chronic pain conditions. Hypnosis can also be effective for minimizing pain associated with burn treatment, surgical procedures, childbirth, and invasive medical diagnostic procedures. The use of hypnosis can allow the patient to respond in an active manner when faced with pain, can reduce the use of medication, and may facilitate medical compliance. Hypnotic interventions have also been proven to be cost effective and may reduce patient care costs in some instances related to improved outcome, use of less pain medication, and shortened procedure duration. Hypnotic suggestion can be used directly to alleviate the experience of pain, to alter the pain sensation, or to provide distraction from pain. Typically the client will eventually be taught to use self-hypnosis once the effective use of suggestions has been demonstrated.

There is evidence that the addition of hypnotic suggestion to behavioral treatment plans provides some advantage in treating habit disorders. Hypnotic suggestions that alter perceptions can be especially useful in these treatments. For individuals trying to quit smoking, hypnotic suggestions to increase the aversiveness of smoking and minimize withdrawal symptoms can be incorporated into a standard smoking cessation protocol. Similarly, treatment for obesity can incorporate suggestions for aversive reactions to unhealthy foods and an enhanced sense of control over eating behaviors. Augmenting treatment with hypnotic suggestions can also increase confidence in the ability to achieve one's goals and can lead to greater compliance with the selected treatment program. Meta-analytic studies suggest that the effects of treatments for obesity and pain (among other conditions) may be enhanced by the inclusion of hypnosis.

One way in which hypnosis can be used in expressive psychotherapies is to help the patient modulate and work through particularly painful emotional experiences. Suggestions can help to productively direct emotional expression and thereby facilitate affect regulations in the service of cognitive mastery. Further, the use of hypnosis may increase access to painful primary process and symbolic material, as logical, critical thinking tends to be suspended. This allows the therapist and patient to develop creative approaches to solving problems in living, with an emphasis on self-efficacy. Again, because of enhanced receptivity to suggestion, it is important that the therapist be knowledgeable in working with the presenting issues, have a clear clinical formulation, and have the wherewithal to treat the patient with or without hypnosis.

It appears that for some patients, hypnosis can increase receptivity, enhance relatedness, and facilitate symptom resolution. This makes hypnosis a useful tool to be integrated into many forms of treatment for medical and psychological problems.

HYPOTHESIS TESTING

Research hypotheses are predictions based on reasoning from a theory or past findings about the results of a study. Ideally, hypotheses are specific and concrete so that they indicate specific criteria needed to test them and can be proven or disproven unambiguously. The criteria used to test hypotheses are called *dependent variables.* The process of generating testable hypotheses serves to clarify the questions being asked about a particular research problem. It forces the researcher to specify the concrete data needed to come to a conclusion about the hypothesis as well as how the data will need to be analyzed.

The statistical procedures used to test a hypothesis have, by convention, been set up on the assumption that any differences in the dependent variables are due to chance. The procedures ascertain the probability that any apparent difference is not an actual difference. Consequently, when hypotheses are examined statistically, they must be represented in the null form (i.e., predict no difference). When the statistical analysis indicates that there is a high probability of there being no actual difference among the dependent variables, the null hypothesis is accepted. When the probability of there being no actual difference is low, the null hypothesis is rejected.

When a research hypothesis is supported, it means that the changes in the data cannot be attributed to chance. It also means that causal factors stated in the hypothesis may explain the changes, but it does not prove that they do as long as there are alternative hypotheses. As a result, the process of theory building is not a matter of proving a hypothesis, but rather of eliminating inadequate hypotheses until one continues to survive attempts at disconfirmation.

If a research hypothesis predicts that the dependent variable will change in a particular direction (e.g., become larger or smaller), then the corresponding statistical hypothesis is analyzed by using what is termed a *one-tailed test,* which focuses on only one end of the sampling distribution and analyzes changes in the hypothesized direction. If it is hypothesized that change could occur in either direction, a *two-tailed test* is used.

When deciding whether to reject or accept a statistical hypothesis, two types of error are possible. A *Type I* or *alpha error* occurs when the hypothesis of no difference is rejected, when in fact there was no real change in the dependent variable. Prior to an experiment, a researcher decides how much he or she is willing to risk a Type I error by choosing a level of significance. The level of significance, or alpha, is the probability of a given change in the dependent variable occurring by chance. The typical level of significance used for rejecting the null hypothesis is $p = 0.05$ or 0.01.

A *Type II* or *beta error* occurs when a hypothesis of no change is accepted, when in fact there has been a change. The chances of making this error decrease if alpha (the level of significance) is increased or if the sample size is increased. Reducing the variance within the sample or increasing the magnitude of the experimental effect can also reduce the chances of a Type II error.

Because the probability of one type of error decreases as the probability of the other increases, a researcher must decide which is preferable in a given situation. In instances in which labeling a chance difference as a genuine difference is costly, a conservative approach can be taken by setting the level of significance low. Alternatively, in instances in which it would be costly to overlook any promising leads, a higher level of significance can be set, thus reducing the chances of a Type II error.

The power of a statistical test is the probability of correctly rejecting the hypothesis of no difference. It is equivalent to 1 minus the probability of a Type II error. The power of a statistical test can be increased by using the methods for decreasing the chances of a Type II error mentioned previously.

Statistical significance is not synonymous with practical significance. A decision about practical significance is made independently of statistical procedures and can only be arrived at by individuals who are aware of the specific situation in which the research findings might be applied.

I

IDENTITY FORMATION

There are numerous theoretical approaches illuminating certain areas of identity development (i.e., Kegan's constructive-developmental approach or Blos's object relations approach), but Erik Erikson's (1963, 1968) psychosocial approach to human development appeals to many professionals because of its utility in many areas: clinical, theoretical, and empirical. Erikson's seminal work stressed the importance of history (personal and societal) and social contexts as influencing individuals' lives; consequently, he incorporated these ideas into his concept of identity formation in adolescence.

Erik Erikson developed the construct of ego identity as an adaptive response to Freud's focus on neurotic personalities. He was interested in the development of healthy personalities and created a lifespan stage theory that addressed the development of the healthy ego. Obtaining a healthy ego identity evolves through unconscious and conscious mechanisms interacting dynamically in a process of discovering the self. According to Erikson, there are certain key crises inherent in different periods of a person's life. These crises reflect the person's social maturity and societal expectations. The crises are then categorized into distinct psychosocial stages of development, at which times certain ego strengths emerge as resolutions of these crises.

A person integrates into his or her ego identity the resolution of the crises for each stage of development. Each stage of psychosocial development culminates in a balance of both *syntonic* and *dystonic outcomes.* A syntonic outcome is a positive experience through which the individual strives to attain and consequently maintain the experience in the overall ego structure. Receiving accolades for achievement in school from a significant teacher is an example of a syntonic experience. Conversely, a dystonic outcome is a negative experience whereby the individual strives to avoid and consequently rectify the experience in the overall ego structure. Being the recipient of a disparaging remark from a significant teacher is an example of a dystonic experience. Healthy psychological development occurs when the number of syntonic experiences outweighs dystonic experiences (Waterman, 1993, p. 53).

Adolescence, the fifth stage of psychosocial development, is the crucial period during which identity formation occurs. It reflects the accumulated syntonic and dystonic outcomes of the prior four stages of development. Identity formation is an integration in the self of the prior outcomes related to earlier stages of development. However, as Erikson noted, the formation of identity does not occur in a vacuum. The culture of society is crucial in how the adolescent integrates the prior stages of development. One's culture is shaped by the contexts in adolescents' lives. Hamachek (1985) uses a metaphor of ego growth rings, much like the growth rings of a tree, to facilitate an understanding of how an adolescent integrates the self in relation to contextual conditions when constructing an identity. Erikson's psychosocial stages of development are imbedded in a series of concentric circles such that the width between each ring of development identifies the context, both positive and negative, of growth. Development that is constricted by the environment and made up of mostly dystonic outcomes would show a shorter width in growth for a particular stage, while development that is enriched or expanded by the environment and made up of mostly syntonic outcomes would show a longer width in growth for a particular stage.

Identity development mirrors the outcomes achieved in various domains in a person's life. Erikson delineated the following identity domains where this mirroring or self-reflection occurs. These are (1) vocation; (2) ideologies (religious, political, and economic); (3) philosophy in life; (4) ethical capacity; (5) sexuality; (6) gender, ethnicity, culture, and nationality; and (7) "an all-inclusive human identity" (Erikson, 1968, p. 42). Through growth and integration in these domains, the adolescent's identity becomes integrated, ideally forming a healthy and stable self.

Marcia (1980) applied Erikson's concepts of ego identity into two operational dimensions of exploration and commitment.

> *Exploration* refers to a period of struggle or active questioning in arriving at various aspects of personal identity, such as vocational choice, religious beliefs, or attitudes about the role of a spouse or parenting in one's life. *Commitment* involves making a firm, unwavering decision in such areas and engaging in appropriate implementing activities. (Waterman, 1993, p. 56)

Relative to these two dimensions of exploration and commitment, Marcia delineated four identity statuses that exist for an individual in later adolescence. These four statuses are (1) *identity diffusion,* (2) *identity foreclosure,* (3)

moratorium, and (4) *identity achievement.* Identity diffused adolescents have not committed to an internally consistent set of values and goals, and exploration is superficial or absent. Identity foreclosed adolescents have committed to a set of values and goals with little or no exploration present. Moratorium adolescents are in the process of committing to a set of values and goals as they are intensely exploring alternatives to their decisions. Identity achieved adolescents have experienced a period of exploration (as in moratorium) and have come to an autonomous resolution of identity by committing to a set of values and goals (Patterson, Sochting, & Marcia, 1993, pp. 10–12; Marcia, 1993, pp. 10–11). These statuses are not static and evolve as one develops. That is why it is not uncommon for some middle-aged adults to change professions or convert to another religion (Kroger, 2000). The culture or context in which one lives provides the framework for instituting a change in the self. Generally these changes lead one through a new phase of moratorium and, finally, achievement. Thus, identity formation involves a dynamic interplay between the intrapsychic self and the contexts in which the person lives.

IDIODYNAMICS AND THE IDIOVERSE

There are three universes in the known cosmos: at one extreme, there is a universe of stellar bodies that requires telescopic observation (astronomic), while, at the other extreme, there is the atomic universe of molecules and other particles (microscopic). Between these two realms exists the human idioverse of experiential events.

It is important to recognize that the three universes have in common, at least hypothetically, the dynamic feature of energy expressed in orbital motion or the equivalent. In the case of stellar bodies, the Earth, as a member of the solar system, revolves around the sun and rotates on its axis through the principles of gravitation. By analogy, the members of the remotely observed galaxies presumably behave similarly, but this analogy is hypothetical. At the other extreme, the atoms, which compose molecules, are governed by components or particles with characteristic orbits. The table of the atomic numbers of the chemical elements and other principles of physics and chemistry have analogous properties to those observed for the solar system. Finally, it is here hypothetically postulated that the human idioverse, with its population of events and its characteristic patterns of repetitive markers, will, in future years, be shown to exhibit similar properties. Nervous energy mediated by the brain and the autonomic nervous system are known to express dynamic characteristics which at this point can only be the subject of speculation.

Idiodynamics is the science of the idioverse: the science of behavior from the standpoint of human individuals (Rosenzweig, 1951, 1958, 1986a, 1986b). The idioverse is conceived to be a population of experiential events. Events are the basic units and are defined and observed phenomenologically.

Origin and Development

Idiodynamics had its origin in three areas of empirical investigation: (1) the experimental redefinition of clinically-derived psychoanalytic concepts; (2) the intensive study of individual mental patients, to obtain an anamnesis through interviews, and by administering projective and psychometric techniques; and (3) the reconstruction of the life and work of creative writers, and selected patients, through an approach called *psychoarchaeology.*

The earliest contribution was a formulation by Rosenzweig in his essay, "The Experimental Situation as a Psychological Problem" (1933). It systematically examined the previous methodological literature of experimental psychology in relation to the evidence of the writer's own recent experimental research. The standpoint was that of the reciprocal interactions of the observer and the subject. These interactions were schematically classified, the terms *observer* and *subject* being replaced by *experimenter* (Er) and *experimentee* (Ee). It was shown that in the early German

literature just such a reciprocal terminology was employed, that is, *Versuchsleiter* and *Versuchsperson.* The special contribution of the paper was a classification of the various typical, reciprocal interactions encountered in experiments. This advance in experimental psychodynamics and social psychology made only a minor impact until about 20 years later when, in the 1950s, Rosenthal and others began to publish their independent findings on "experimental bias" and related concepts (Rosenthal, 1959, 1966).

This first formulation of the complementarity between experimenter and experimentee (Rosenzweig, 1933) was followed by several other similar ones. In "Schools of Psychology: A Complementary Pattern" (Rosenzweig, 1937), the natural division among the then-prevalent schools was shown to represent a complementary pattern in which a certain type of *problem* achieved resolution by *methods* (and related concepts) appropriate to the problem. In "Some Implicit Common Factors in Diverse Methods of Psychotherapy" (Rosenzweig, 1936), Sherrington's neurological principle of the "final common pathway" (CF/CP) was, without deliberate awareness, applied to the very different field of psychological therapy. Each of these formulations stressed a different kind of complementarity, but all were implicitly guided by the overriding principle.

Another complementary distinction made in idiodynamics was the threefold manner in which behavior may be alternatively *explained: nomothetic, demographic,* and *idiodynamic.* These three explanatory modes, known as "norms," were first designated as universal, group, and individual. They were illustrated by reviewing their roles as modes of association in the history of psychology (Rosenzweig, 1950). The nomothetic modes of association were first described by the early Greek thinkers who distinguished the categories of similarity, contiguity, and so forth. Even in present-day theories of learning, such categories are employed. After Galton's work was published (1879–1880), these categories became the basis for experimental studies of word-association, conducted in Wundt's laboratory of experimental psychology in Leipzig (Trautscholdt, 1883). It was recognized early that certain groups of individuals, including mental patients with a given diagnosis, produced associations peculiar to or characteristic of the group. In this way certain kinds of associations consistently produced by an individual helped to classify him or her as belonging to a given diagnostic group (e.g., the clang associations of the manic patient). Later, in Jung's research on complexes (Jung, 1918), the peculiar significance of certain word associations were seen as pointing to uniquely individual constellations (or complexes) of thought, image, and feeling in a particular person. Jung's insight anticipated the *idiodynamic* orientation.

These three explanatory modes are now designated as *nomothetic, demographic,* and *idiodynamic* to avoid the quantitative emphasis misleadingly implied by the earlier terminology. That confusion is evident in the writing of Gordon Allport (1937), who proposed a new conceptualization of personality that (implicitly) equated each mode with the size of a population. In this way Allport tended to confound the *idiodynamic* with the *idiographic* (Rosenzweig & Fisher, 1997).

Concepts

The idioverse has (1) a core matrix and (2) a *biogenic* medium, on one side, and a *sociogenic* medium, on the other, both of which contribute to the core matrix. These media overlap and converge at the matrix *idiodynamically.* The three types of norms shown in Table 1 are to a considerable extent aligned with the three milieus, shown in Figure 1: the *biogenic,* tending to be used nomothetically; the *sociogenic,* demographically; and the matrix of the idioverse, aligned with *idiodynamic* norms.

There are also three levels of communication by which

Table 1. Three Types of Explanatory and Predictive Norms

Type	Description
Nomothetic (Universal)	Functional principles of general psychology considered valid by and large.
Demographic (Group)	Statistical generalizations derived from particular cultures or classes of individuals.
Idiodynamic (Individual)	Distinctive markers recurring in a given, single population of events (idioverse).

Note: Each type of norm not only involves a different mode of understanding but also implies a cognate basis for predicting and/or controlling behavior.

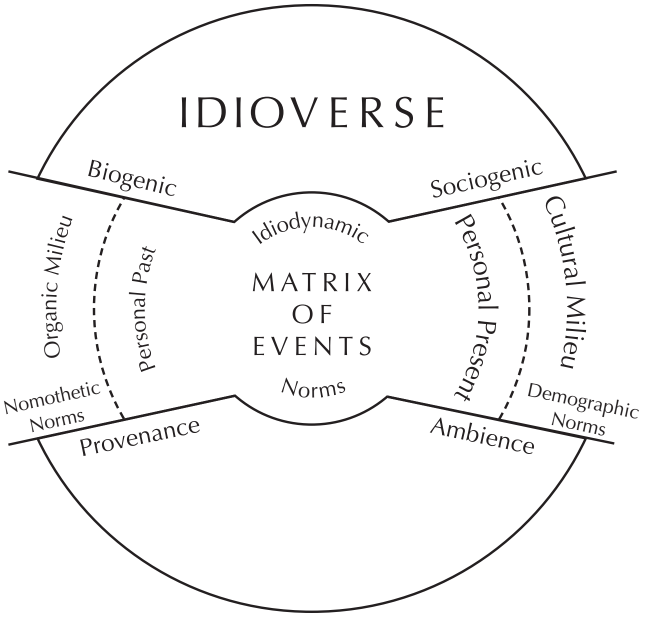

Figure 1. The Idioverse.

the idioverse can be meaningfully understood: the *immediate* or literal level, the *intermediate* or allusive, and the *inframediate* or intimate (Rosenzweig, 1986b). These correspond roughly to the three layers of meaning depicted in the fourteenth century by Dante Alighieri and called by him the *literal,* the *allegoric,* and the *mystical* (Haller, 1973). In the present formulation the first level is similar to Dante's; the second involves not only possible allegory but also other modes of allusion; and the third, instead of being mystical, is recognized as disguised autobiography or other intimate details.

The three levels of communication may be employed to reveal the total meaning inherent in a given idioverse. This technique of discovery is named *psychoarchaeology.* The three levels are studied concurrently, with the assumption that they will not necessarily be represented with equal strength in every production (see Rosenzweig, 1987, for a detailed example of psychoarchaeology).

Psychoarchaeology can be employed with documents such as psychotherapy transcripts, diaries, letters, and the data yielded by projective (psychological) techniques. But the most rewarding results are available in the imaginative productions of creative writers, the elite of whom are almost compulsively involved in veiled self-exposure (Rosenzweig, 1992).

IDIOGRAPHIC–NOMOTHETIC PSYCHOLOGY

Social scientists may choose to formulate either idiographic or nomothetic interpretations of phenomenona. These terms were coined by Wilhelm Windelbrand to describe the work of the natural sciences on the one hand, and, on the other hand, the cultural or human sciences, in which individual cases were studied. An essential conflict defines the two points of view. Scientific generalizations are assumed to be nomothetic or law-like. But for these predictions to be used, they must be applied to particular cases, and individual cases (idiographic analysis) may not conform to general laws.

Idiographic science involves the intensive analysis of

single cases, with the attempt to formulate interpretive statements pertaining only to the case or to the class of phenomena that the case represents. Idiographic interpretations are based on the particularities of a given case. Their claim to validity rests on the power of the descriptions produced by the researcher. These descriptions attempt to capture the perspectives of those studied. It is assumed that different interpretations are likely to be meaningful in different realities. Any interpretation will be shaped by local particulars and interactions between the researcher and those studied.

Nomothetics rests on the claim that scientific laws can be formulated only statistically, through the study and analysis of a large number of randomly selected cases. Nomothetic generalizations are assumed to be time and context free. They do not depend on the specifics of a particular context or case.

The conflict over idiographic and nomothetic models of science and inquiry has plagued the social sciences in general and psychology in particular since the beginning of the twentieth century, although the origins of the debate can be traced to the rise of the human disciplines in the eighteenth and nineteenth centuries.

Fundamental assumptions regarding the nature of inquiry, philosophies of science, and the purposes of the social and psychological sciences are involved in the idiographic–nomothetic debate. Arguments by feminist scholars and scholars of color have sharpened this debate. Such individuals believe that the methods of nomothetic science have often been used as tools of oppression, producing knowledge that is biased in the direction of a male-dominated science. Postpositivist critical theorists and postmodernists also have criticized nomothetic science and its assumption that knowledge is free of bias, personal values, and political ideology. These theorists argue that nomothetic science is often used as a form of political control.

Stated most succinctly, the issue revolves around whether psychology will be a causal science seeking general laws of human behavior or an interpretive, praxis-based discipline seeking greater and deeper understanding of social and psychological processes.

Nomothetic investigators reject idiographic interpretations. They regard them as being unscientific or journalistic. Conversely, ideographic researchers argue that nomothetic studies are of little value because all interpretations are assumed to be contextual and specific to given cases.

Nomothetic Psychology

Nomothetic psychology seeks the discovery of scientific, statistically valid, generalizable laws regarding human behavior. Certain assumptions underlie this point of view. First, causal explanations of social phenomena are sought. A variable-analytic language that rests on the operationalization of variables and concepts is employed, and strict cause–effect models of inference are used. Second, the quantification of mental and behavioral processes is pursued. Third, it is assumed that causal propositions formulated on the basis of the careful study of randomly selected subjects can be generalized to nonobserved populations. Fourth, the nomothetic scientist endeavors to construct (typically) nonnaturalistic experimental laboratory settings in which scientific observations are gathered. Fifth, to the degree that the findings from idiographic methods are used in nomothetic science, they are frequently regarded as useful only for explanatory, descriptive, or illustrative purposes (e.g., pretesting). Sixth, nomothetic theories are deductive and probabilistic and offer functional explanations of phenomena. Idiographic psychology and its methods are regarded as useful only to the extent that they contribute to the construction of scientific theories that meet the foregoing criteria.

Idiographic Psychology

In twentieth century psychology, the work of Gordon Allport is most commonly associated with idiographic psychology, which rests on certain assumptions and methods. In the words of Allport, it is assumed that "psychology will become *more* scientific (i.e., better able to make predictions) when it has learned to evaluate single trends in all their intrinsic complexity, when it has learned how to tell what will happen to *this* child's IQ if we change his environment in a certain way." Allport's assumption requires a deep and sustained interest in the study and analysis of a single case over a long period of time; longitudinal studies are required.

Specifics, not universals, are explored by the idiographic psychologist. Because each individual is assumed to be unique, the psychologist must work with a theory and a set of methods that retain and reveal individual differences. In addition, there is an attempt to permit the individual subject to speak in his or her own language, to secure the meanings that hold for persons in their life world, and to capture those meanings and experiences with methods that are relatively unstructured, open-ended, projective, and interpretive. Personal documents and life histories are used, as are unobtrusive and indirect measures of personality, in combination with other methods and techniques in a triangulated fashion. Naturalistic research conducted in the everyday situations of individuals is favored by the idiographic psychologist.

Etic and Emic Investigations

The contrast between nomothetic and idiographic psychologies may be compared with the *etic* and *emic* controversy in recent anthropological theory. Etic investigations are external, comparative, and cross-cultural. Distance from particular cultures is sought so that general patterns can be discovered. The specific, unique configurations of meaning that pertain within a single culture are set aside in an effort to discover cross-cultural universals. Emic in-

vestigations study cultural meanings from the inside, seeking to uncover the cognitive categories and classification systems that members of particular cultures and cultural groupings use. Emic investigations are particularizing; etic investigations are generalizing. Furthermore, emic investigations are framed from the insider's point of view. Emic studies implement the idiographic approach to science, whereas etic studies are committed (usually) to the nomothetic approach.

Thick Versus Thin Descriptions

Thick, as opposed to thin, descriptions go beyond the mere reporting of fact, correlational coefficients, or significance tests to the level of detail, emotion, meaning, nuance, relationship, and interaction. Thick descriptions are emic and idiographic. If combined with the traditional methods of the idiographic psychologist, thick descriptions would permit a deeper probing of the underlying personality and interaction patterns that idiographic psychologists endeavor to discover and understand. Nomothetic psychology primarily rests on thin descriptions, etically discovered.

Progressive–Regressive Method of Sartre

Jean-Paul Sartre proposed a method of inquiry that, in many significant respects, synthesizes the above discussion. The progressive–regressive method of investigation seeks to situate and understand a particular subject or class of subjects within a given historical moment. Progressively, the method looks forward to the conclusion of a set of acts or projects undertaken by the subject (e.g., the production of a novel). Regressively, the method looks backward to the conditions that embed and embody the projects and practices of the subject. By moving forward and backward in time, the subject and his or her projects are situated in time and space. The unique differences in the person's life are revealed while the commonalities and similarities shared with others are likewise revealed. The method also is analytic and synthetic, in that analysis is woven through the main threads of the subject's life in a synthesizing, interpretive fashion.

Feminist Inquiry

Recent developments in feminist scholarship expand the idiographic-emic approaches in new directions. More reflexive epistemologies that place the investigator in the center of the research process are being developed. African American, Hispanic, and Third World feminists are studying how colonial (positivist–nomothetic) discourses misrepresent the lives of women in diverse contexts. Other scholars are challenging the objective biases of the nomothetic approach. This perspective, they assert, assumes that a static world of objects can be studied (not created) by the methods of objective science. They contend that the scientist creates the world that is studied. These researchers note that studies of women have traditionally treated females as static objects to be viewed through the lens of an objective (male-dominated) science. Other feminist scholars are experimenting with new writing forms, including autoethnographies, performance texts, and poetry.

THE INSULIN-LIKE GROWTH FACTOR 1 (IGF-I): A KEY MODULATOR OF NEUROGENESIS AND COGNITIVE FUNCTIONS

Activity of insulin-like proteins was discovered in 1957. The precise action of insulin-like growth factor I (IGF-I) remained poorly understood until the production in the 1980s of recombinant human IGF-I. This trophic factor has been well characterized as a factor mediating growth hormone action (Jones & Clemmons, 1995; Isaksson, Ohlsson, Nilsson, Isgaard, & Lindahl, 1991). IGF-I is found in high levels in the blood and is believed to originate mainly from the liver (Pankov, 1999). The detection of the IGF-I gene using molecular techniques showed its presence in several organs, including the brain (Rotwein, Burgess, Milbrandt, & Krause, 1988). Substantial evidence supports the importance of IGF-I and insulin in normal development and maintenance of adequate neuronal functions throughout the entire lifespan. The structure of IGF-I is quite similar to insulin (Isaksson et al., 1991). Interestingly, researchers have suggested that the level of insulin in the brain is quite low and that, in fact, IGF-I could act as insulin in the central nervous system. IGF-I has the capacity to bind to the entire IGF receptor family, including the insulin receptor. High densities of binding sites for IGF-I and insulin are discretely and differentially distributed throughout the brain, with prominent levels localized to the hippocampus. IGF receptors are produced by numerous neuronal and non-neuronal cell types. IGF-I is a well-established stimulant of cell growth, proliferation, and differentiation, and can stimulate glucose transport and prevent cell death (Doré et al., 1997b). These later effects are crucial for survival of postmitotic neurons.

The authors have previously demonstrated that IGF and insulin receptors are tightly regulated and subject to rapid and chronic changes after a multitude of surgical and pharmacological lesions (Doré et al., 1997c; Doré et al., 1996; Kar et al., 1997a). Both the IGF-I and insulin receptors possess similar tyrosine kinase activities, and binding of the ligand to the α-subunit of the receptor induces the autophosphorylation of the β-subunits. One of the key phosphoproteins is the insulin receptor substrate (IRS), which

interacts directly with other intracellular signaling substrates, including the phosphatidylinositol 3-kinase/AKT kinase pathway and various other downstream transcription factors (Zheng et al., 2002). Activation of these pathways has been shown to be protective in several chronic and acute neurodegenerative conditions (for example, using models of Huntington and hypoxia (Humbert et al., 2002; Scott et al., 2002)).

IGF-I and Insulin Receptor Levels in Cognition

No significant differences are found in IGF-I or insulin receptor levels in any subfields of the hippocampus of young versus aged rats (Doré, Kar, Rowe, & Quirion, 1997). Furthermore, deficits in cognitive performance do not relate to alterations in the levels of these receptors in aged impaired (AI) compared to aged unimpaired (AU) rats. It thus appears that IGF-I and insulin receptor binding sites are not markedly altered during the normal aging process in rats, and cognitive deficits observed in the Morris water maze are not mirrored by changes in these markers. Accordingly, spatial learning deficits observed in the AI group are not due to alteration in IGFs and/or insulin receptor sites. However, these data do not rule out the potential of altered IGFs or insulin postreceptor signaling efficacy between AU and AI groups (discussed later). These results can also be related to those obtained in the human brain. No significant differences in the levels of IGF-I binding sites were reported in the human cerebral cortex with respect to age, postmortem delays, or medications (Crews, McElhaney, Freund, Ballinger, & Raizada, 1992). In contrast, specific IGF-I binding was increased in the cerebral cortex of Alzheimer's disease (AD) patients, possibly in response to decreased levels of IGF-I (Jafferali, Dumont, Sotty, Robitaille, Quirion, & Kar, 2000).

Regarding insulin receptors, an earlier study reported results similar in 22-month-old (compared to young) Wistar rats, with no significant changes being observed in any brain regions, except for a slight decrement in olfactory bulbs (Tchilian, Zhelezarov, Petkov, & Hadjiivanova, 1990). In contrast, insulin receptor binding was reported to be decreased in aged mouse brain homogenates (Zaia & Piantanelli, 1996). These differences are likely to be species-related. A study on the ontogenesis of the insulin receptor using synaptosomal membranes revealed a general decrease in the human cerebral cortex from development to adulthood (Potau, Escofet, & Martinez, 1991).

Insulin and/or IGF-I Resistance with Aging

In general, aging is associated with insulin resistance. Is it possible that neurons also become resistant (or somewhat diabetic) and that their uptake of glucose is not as efficient to satisfy energy demand? In the periphery, previous studies showed age-related alterations in tyrosine kinase activity (Ruiz et al., 1992). Moreover, despite normal levels of insulin receptors in 20-month-old Wistar rats, it was shown that receptor autophosphorylation was reduced by 25%, in addition to decreased IRS-1 levels. Moreover, insulin-stimulated IRS-1 association with phosphatidyl-inositol 3-kinase (PI3-kinase) was decreased by 70% in the liver and 98% in muscles of 20- versus 2-month-old rats, with no change in PI3-kinase level; the phosphorylation of IRS-2 followed a similar pattern (Carvalho et al., 1996). Interestingly, insulin could not induce sodium/potassium-ATPase activation and plasma membrane hyperpolarization of certain cell types in aged Wistar rats (Frolkis, 1995). It was also demonstrated that peripheral insulin resistance in 24-month-old Wistar rats was accompanied by an impairment in insulin-sensitive, glycosyl-phosphatidylinositol-dependent cellular signaling (Sanchez-Arias et al., 1993). One study divided 24- to 27-month-old Wistar rats into three groups having mild, moderate, and severe reduction in maximal insulin-related kinase activity and found that deficits in the mild and moderate subgroups could be reversed by extensive autophosphorylation (Nadiv, Cohen, & Zick, 1992). It remains to be established whether in aged rats differential alterations in these markers could be correlated with cognitive performance and comparable changes in the IGF-I receptor signaling pathway.

A study was also designed to assess whether cognitive deficits in aging could be partially overcome by increasing the availability of IGF-I in the brain (Markowska, Mooney, & Sonntag, 1998). Male rats of two ages (4 and 32 months) were preoperatively trained in behavioral tasks and subsequently implanted with minipumps to infuse IGF-I or a vehicle into the cerebral ventricles. Animals were retested at 2 and 4 weeks. IGF-I improved working memory in the repeated acquisition and object recognition tasks. An improvement was also observed in the place discrimination task, which assesses reference memory. Moreover, injection of IGF-I antisense oligonucleotides in the inferior olive region elicited a complete inhibition of conditioned eye-blink learning in freely moving rats (Castro-Alamancos & Torres-Aleman, 1994). Furthermore, insulin treatment prevents deficits in water maze learning and long-term potentiation (LTP) in streptozotocin-diabetic rats (Biessels et al., 1998). Taken together, these data indicate a potentially important role for IGF-I (and insulin) in the reversal of age-related behavioral impairments in rodents.

The growth hormone (GH)/IGF-I axis is known to be involved in aging of physiological functions. Recent studies indicate that the GH/IGF-I axis may also be associated with cognitive functioning. For example, Aleman et al. (1999) determined whether age-related decline in circulating IGF-I levels were correlated with cognitive performances. Twenty-five healthy older men with well-preserved functional ability participated in the study. Neuropsychological tests of general knowledge, vocabulary, basic visual perception, reading ability, visuoconstructive ability, perceptual–motor speed, mental tracking, and verbal long-term memory were administered. Performance on the last four tests declined with age, whereas the first four were not as

sensitive to aging. Interestingly, the authors found that plasma IGF-I levels were significantly correlated with performances (controlled for education) on the Digit Symbol Substitution test and the Concept Shifting Task, two tests measuring perceptual–motor and mental processing speed. Subjects with higher IGF-I levels performed better on these tests. These data support the hypothesis that circulating IGF-I may play a role in the age-related decline of certain cognitive functions, especially those related to the speed of information processing (Aleman et al., 1999). In another study, Rollero et al. (1998) reported that plasma IGF-I levels were directly correlated with cognitive function as assessed using the Mini Mental State Examination; scores and IGF-I levels were lower in patients with the most advanced cognitive deterioration.

Importance of Controlling Glucose Homeostasis

In aged rats and humans, impaired glucose regulation has been correlated with poor memory performance. Aged (22 to 24 months) and young (3 months) rats were assessed in a battery of behavioral tests that included tasks of learning and place navigation. Following evaluation all animals were analyzed for their local glucose utilization. The decline in performance correlated significantly with the decrement in regional glucose utilization (Gage, Kelly, & Bjorklund, 1984). Moreover, performance in these two tests showed significant correlation with glucose use in brain regions associated with learning processes. These results suggest that learning impairments in aged rats may be related to decreases in glucose utilization.

Interestingly, intraperitoneal glucose injections result in improved learning performance (Long, Davis, Garofalo, Spangler, & Ingram, 1992). For example, effects of a pretraining intraperitoneal glucose injection on learning and memory were tested using the Morris water maze. Glucose injection before a block of trials enhanced spatial memory performance in mice (Li et al., 1998). In aged cognitively impaired Wistar rats, significantly reduced cerebral glucose utilization was observed in various regions associated with learning and memory processes (Wree et al., 1991). Treatment of both neuronal and glial cultured cells with insulin and IGF-I induced a time- and dose-dependent increase in the steady state levels of glucose transporter mRNA (Werner et al., 1989). Severe decreases in brain insulin levels were also observed in aged rabbits, and the expression of the glucose transporters in the Wistar rat brain is altered during aging (Vannucci, 1994). Interestingly, herpes simplex virus vectors bearing a glucose transporter gene were found to protect neurons against a one-hour focal ischemic insult in rats (Lawrence et al., 1996), suggesting a possible treatment strategy to increase glucose transporter availability in the aged brain. Hence, in spite of apparently normal levels of IGF-I and insulin receptor sites in the AU and AI Long Evans rats (discussed earlier), alterations in related signaling pathways and glucose transporters could lead to decreased cognitive abilities. It is thus possible that altered cellular IGF and/or insulin responsiveness is a general feature of aging having functional significance in neurodegenerative diseases by affecting cognitive abilities. Interestingly, experimental desensitization of brain insulin receptors in aged Wistar rats induced abnormalities in glucose utilization, membrane phospholipids, and monoaminergic metabolism, resembling some of the disturbances seen in AD (Hoyer, Muller, & Plaschke, 1994). Links between the onset of AD and diabetes are thus possible, because the latter is a risk factor in AD (Fanelli et al., 1995; Vanhanen et al., 1998).

Using rat hippocampal sections, the authors observed that IGF-I modulates potassium-evoked acetylcholine (ACh) release (Kar et al., 1997b). These data suggest a direct role for IGF-I and its receptors in the regulation of transmitter release in the central nervous system. Evidence indicates that systemic glucose treatment enhances memory while producing a corresponding increase in hippocampal acetylcholine (ACh) release (Ragozzino, Pal, Unick, Stefani, & Gold, 1998). Unilateral intrahippocampal infusions of glucose were examined for enhanced spontaneous cognitive performance and corresponding increases in ACh release. Twelve minutes after a unilateral infusion of glucose, rats were tested in a cross maze for spontaneous alternation behavior with concurrent microdialysis collection. Glucose infusions significantly increased cognitive scores compared to controls, and behavioral testing resulted in increased ACh output in the hippocampus. These results suggest that glucose may enhance cognitive abilities by modulating ACh release. Accumulated evidence (Kar et al., 1997b; Knusel, Michel, Schwaber, & Hefti, 1990) suggests that IGF-I acts as trophic factor as well as a rapid neuromodulator for selected populations of cholinergic neurons, and thus may be of relevance to certain degenerative diseases, particularly AD, in which decreased levels of cholinergic markers are associated with impairments in cognitive functions (Perry, 1986; Quirion, 1993; Selkoe, 1994). In support of a possible role for IGF in AD, it has been shown that IGF-I binding sites are increased in the cortical areas affected by this disease (Crews et al., 1992), and IGF-I can protect/rescue cultured hippocampal neurons from β-amyloid-mediated toxicity (Doré et al., 1997a). Interestingly, glucose levels may also modulate the production and the toxicity of β-amyloid fragments (El Tamer, Raikoff, & Hanin, 1998; Hoyer et al., 1994; Mark, Pang, Geddes, Uchida, & Mattson, 1997), again associating the beneficial effect of IGF-I and brain glucose metabolism.

Crucial Role of IGF-I in Neurogenesis

In most brain regions of highly developed mammals, the majority of neurogenesis is terminated soon after birth. However, new neurons are continually generated throughout life in at least two areas of the adult mammalian brain, the subventricular zone of the lateral ventricle and the sub-

granular layer of the hippocampal dentate gyrus (Anderson, Aberg, Nilsson, & Eriksson, 2002; Magavi & Macklis, 2002; Reynolds & Weiss, 1992), although the exact phenotype of the most primitive cell in these areas is not yet known. The proliferation, migration, differentiation, and survival of these progenitor cells are regulated by complex interactions between a number of internal and external factors. Enriched environment, psychosocial stress, learning, exercise, age, and a variety of neurotransmitters and growth factors (especially IGF-I) have been shown to modulate the number of new neurons (Magavi & Macklis, 2002).

IGF-I has also been shown to influence not only the developing nervous system, but also adult neurogenesis (Anderson et al., 2002). In vitro and in vivo studies indicate that IGF-I increases proliferation and, in some experimental paradigms, also promotes differentiation toward a neuronal cell lineage (Aberg, Aberg, Hedbacker, Oscarsson, & Eriksson, 2000). However, it is still unclear whether the net increase in new neurons is due to a neuroprotective/survival effect of IGF-I on newborn neurons, rather than an effect on neurogenesis itself (Anderson et al., 2002). Another indication that IGF-I influences neurogenesis under physiological conditions arises from a recent study that has demonstrated that exercise-induced neurogenesis is mediated by uptake of IGF-I into the brain parenchyma. Administering an antibody that blocked passage of systemic IGF-I to the brain during running attenuated hippocampal neurogenesis (Trejo, Carro, & Torres-Aleman, 2001). Hippocampal neurogenesis declines with age, caused at least partially by naturally increased glucocorticoid levels, since adrenalectomized aged rats have levels of neurogenesis very similar to those of young rats (Magavi & Macklis, 2002). Intracerebroventricular administration of IGF-I to old rats increased neurogenesis and reversed cognitive impairments (Lichtenwalner et al., 2001). Stress and depression also inhibit neurogenesis, possibly via the associated reductions in serotonin or increases in circulating glucocorticoids (Magavi & Macklis, 2002). As both of these changes have the potential to downregulate IGF-I production by neural cells, stress may inhibit neurogenesis indirectly via downregulation of IGF-I.

Potential Therapeutic Approaches

It has been reported that intraventricular and subcutaneous supplementation of IGF-I protects immature and adult brains against hypoxic-ischemic injury and ischemia (Hoffmann, Schaebitz, & Schwab, 1999; Loddick et al., 1998; Tagami et al., 1997; Zhu & Auer, 1994). Brain injury is often associated with an increase in IGF levels (Gluckman et al., 1992; Sandberg Nordqvist et al., 1996) and IGF receptors (Bergstedt & Wieloch, 1993). IGF-I has been extensively used clinically (Lewis et al., 1993; Yuen & Mobley, 1995) and has been studied with respect to growth delay, diabetes, and catabolic disorders. Its safety has been well established, although some side effects must be considered, especially in relation to chronic use. One of the counterindications is that IGF-I, due to its characteristic growth-promoting activities, could promote the progression of some tumors (Lewis et al., 1993; Lonning & Lien, 1995). Hence, the design of mimetics, devoid of the side effects of IGF-I, should be developed.

In that regard, a few strategies are worth considering. One approach relates to alterations of IGF-I binding to IGF-binding proteins (IGFBP) in order to increase the level of IGF-I, while the other strategy is based on the design of nonpeptidic mimetics. It is well known that the action of IGF-I is modulated by the IGFBPs (six different forms are well known) (Jones & Clemmons, 1995), which form high-affinity complexes and under most circumstances inactivate IGF-I. It has been suggested that displacement of this large pool of endogenous IGF-I from the binding proteins could elevate free IGF-I levels to elicit neuroprotective effects comparable to those produced by the administration of exogenous IGF-I (Loddick et al., 1998). It was shown that a human IGF-I analog [$Leu^{24,59,60}$ Ala^{31}hIGF-I] with high affinity for IGF-binding proteins, but no biological activity at the IGF-I receptors, increased the levels of free, bioavailable IGF-I in the brain. Intracerebroventricular administration of this analog up to one hour after an ischemic insult to the rat brain had a potent neuroprotective action comparable to that of IGF-I. This ligand also attenuates losses of pyramidal neurons in the hippocampus in a model of toxicity induced by quinolinic acid. Hence, this may represent a novel strategy to increase free IGF-I levels in the brain.

The second strategy is very challenging. It is based on the design of nonpeptidic mimetics. Considering that large polypeptides such as IGF-I do not readily cross the blood–brain barrier, the development of a nonpeptide mimic would be ideal. Recently, a team of researchers has shown the feasibility of this approach by developing L-783,281, a nonpeptidyl mimic acting as an agonist on the insulin receptor (Zhang et al., 1999). A similar strategy could lead to the characterization of an IGF-I mimetic on the basis of similarities between IGF-I and insulin receptors.

In conclusion, knowing the pleotropic actions of IGF-I and insulin on neuronal and nonneuronal cells following injuries, an IGF-I treatment could have therapeutic applications in a number of neurodegenerative disorders, in traumatic brain and spinal cord injuries, and in aging. Several clinical trials have suggested the potential beneficial effect of IGF-I in the nervous system, especially in amyotrophic lateral sclerosis (Lou Gehrig's Disease; Lewis et al., 1993). Development of IGF mimetics is now imperative in order to directly assess the usefulness of IGF-I-like drugs in the treatment of neurodegenerative diseases. A better understanding of the links between IGF-I, brain glucose metabolism, and neurogenesis could also lead to the development of new drugs that would reduce memory loss in disorders such as Alzheimer's disease and other forms of dementia and age-related neurological conditions.

ILLUSIONS

Illusions are misperceptions of the environment. The essential notion of an illusion is that it leads the perceiver to misjudge the stimulus, to have a nonveridical perception. The Müller–Lyer illusion (Figure 1) is a visual illusion, probably the most studied of all visual illusions, in which the perceiver misjudges the length of lines. The lines are equal in length, yet the one on the left is judged to be approximately 25% longer than the other. The illusion has been used to illustrate the unreliability of the senses. Stage lighting, makeup, dress fashions—our visual world is full of the practical application of illusionistic principles.

Illusions are an important part of survival for many species. *Protective coloration* means that an animal takes on coloration similar to that of the environment for protection. Some species have ways to hide in shadows by shading that makes it hard to localize the object and dark streaks that camouflage a conspicuous eye (e.g., the raccoon). Blending in with the background indeed creates a misperception, but not a significant distortion, as when one attributes distance to a physically near object.

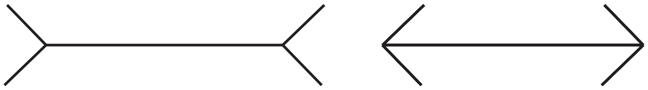

Figure 1. The Müller–Lyer illusion. The two horizontal lines are of equal length, but the line on the left appears to be much longer. To make the lines appear subjectively equal, the line on the right must be approximately 25% longer than the one on the left.

We have no systematic ecological classification of all the illusions in nature and in daily life. Illusions occur in all sense modalities. Best studied are the visual illusions. The Müller–Lyer visual illusion already mentioned is also a tactual illusion. In the horizontal–vertical illusion, a horizontal line is bisected by a vertical one of equal length, but the vertical line appears longer. The Poggendorf illusion has an oblique line that intersects two parallel lines. The portion between the parallel lines is blank, and the oblique line appears to exit somewhat below the point where one would infer that it should. The Ponzo illusion has two approaching lines, as in the linear projection of a road in a picture, in which the distant part seems to converge. Two equal lines between the converging lines, one near the front and the other one near the back of the two lines, seem to be of unequal length, the farther line appearing longer.

The ambiguity of empty visual fields and unusual contexts is responsible for many illusions. A fixed dim light in the dark seems to move—an illusion known as the *autokinetic effect,* exhibited by dim stars on a summer night.

The proprioceptive system is responsible for many illusions, one being the drunken walk of the experienced sailor who feels the ship as steady and the dry land as heaving. The aircraft pilot catapulted from a carrier sees objects appear to rise (the oculographic illusion) while the pilot's body feels tilted backward (the oculogravic illusion). The airplane may seem to be climbing too fast, but corrective action—putting the nose of the aircraft down—may result in a crash into the sea. The illusion is particularly compelling at night when visual references are lacking.

Sound localization is ambiguous and is helped by a visual reference. Thus sound is ascribed to the dummy, not to the ventriloquist (the ventriloquist effect). High-pitched sounds, particularly continuous sounds of a single note, are difficult to localize.

The cutaneous "rabbit" is an illusion of localization, of knowing precisely *where* taps are felt on the skin. If one has three contactors four inches apart on the forearm and gives the lower one five separate taps, then the middle one five taps and the last one five taps, the feeling is not of bursts of pulses at three different places, which is what actually happens, but rather of 15 pulses spread out over the forearm, like a "rabbit" running up the arm. This is because localization on the skin is very imprecise. Similarly with hearing: If seven successive sounds are spread over three speakers, a person hears seven sounds in different places—an auditory "rabbit." The visual fovea is very accurate for spatial localization, but successive lights in the periphery of the eye can also give the illusion of coming from more places than are actually in the source. The "rabbit" is multisensory.

Taste illusions are illusions in which the taste of one substance influences the subsequent taste of another. Salt can

make water taste sour, and sucrose can make water taste bitter.

IMPLOSIVE THERAPY

A behavioral procedure devised by T. Stampfl in the 1950s, implosive therapy hypothesizes that neurotic intense anxiety develops as an avoidance mechanism for coping with repressed traumatic experience and that the relative success of avoidance enables anxiety to persist. In implosive therapy, a patient's anxiety is increased to an almost intolerable level by imagining a series of provoking cues, described either by the therapist or by the patient (with the therapist's assistance), until the anxiety dissipates. Proponents believe the technique reinforces anxiety control and extinguishes related public responses by depriving the anxiety of its avoidance function.

IMPULSIVITY

Impulsivity is a complex personality dimension that relates to the control of thoughts and behavior. At the extreme it becomes symptomatic of a wide range of impulse control disorders. At less extreme levels it characterizes tendencies to influence behavior in coping with everyday life experiences. Marketing experts are well aware of the role of impulsivity in everyday life decision-making. For example, the displays of magazines and other sundry items at checkout counters in stores are carefully chosen to provide cues for triggering impulsive buying. Impulsive buying can be defined as purchasing a product you had not intended to buy and did not need. If done infrequently, it is not pathological behavior. If done to the extent that it becomes "uncontrollable," it can be pathological. In this respect, impulsivity is similar to blood pressure. Blood pressure, like impulsivity, falls on a continuum from low to high, with the "disorder" of hypertension being defined by the level of the blood pressure and the frequency of elevation. Also, like impulsivity, individuals who have persistently elevated blood pressure may have a different biology and respond differently to treatment than individuals with occasional elevations of blood pressure.

In a general sense, impulsivity is part of a behavioral inhibition system that interacts with behavioral activation or "impulse" systems. The range of impulses in the activation system is broad, as evidenced by the number of behavioral disorders that include impulsivity as a symptom. Examples include disorders of personality (e.g., antisocial and borderline), eating, substance abuse, Attention-Deficit/Hyperactivity Disorder, and impulsive aggression (Intermittent Explosive Disorders).

The characteristics of impulsivity as manifest in these disorders attest to its complexity. Impulsive responses are unplanned and usually unconscious. The cues that trigger the responses can be internal thoughts or external stimuli. The behaviors often result in social sanctions which, even though part of the conscious awareness of the impulsive person before committing the impulsive act, are usually not effective enough in themselves to prevent the acts from occurring. Persons who commit impulsive acts that have negative consequences often experience regret or even remorse after the act because they "knew better." Yet their lack of control of these adverse behaviors will continue until special efforts are made to intervene.

Impulsivity is being widely researched because of its pervasive role in selected psychiatric disorders. One of the problems with researching a complex personality trait like impulsivity is that an interdisciplinary research approach is necessary to understand its complexities. This is not a unique problem for impulsivity research, but research on personality and psychopathology in general suffers from the lack of a model that synthesizes research findings from different disciplines. The lack of an overarching model appears, however, to be changing slowly. Rather than simply noting the importance of cross-disciplinary research, researchers have begun to develop models that recognize the need to study impulsivity and other complex personality traits by synthesizing data from different disciplines within a discipline-neutral framework. This change in theoretical contexts has all of the characteristics of a Kuhnian paradigmatic shift for psychopathology and personality research. Within these emerging models, four categories of constructs and related measurements are recognized: biological, behavioral, social/environment, and cognitive. Obviously, impulsivity will be measured differently within the disciplines represented by each of these four categories. However, the goal is not simply an "adding together" of measurements, but rather the use of theories to synthesize

the multimodal measurements. A wide number of measurements within each of the four categories have been used to measure impulsivity.

An example of a *biological* substrate of impulsivity was the identification of an electrical pattern of brain activity recorded while subjects solved cognitive tasks. One of these patterns includes a positive peak of electrical activity that occurs about 300 milliseconds after a relatively rare visual stimulus is presented, also known as a "P300." This peak is significantly smaller in high impulsive subjects and has been related to efficiency of the central nervous system (CNS) in processing information. As measured using this technique, high impulsive subjects process probability-related visual information less efficiently. Another biological characteristic of impulsivity is lower levels of the CNS neurotransmitter serotonin among high impulsive subjects. This has led, in some instances, to the successful intervention in selected impulse control disorders using psychopharmacological agents that increase CNS serotonin levels. Although many of the biological measures appear to be sensitive to levels of impulsivity, it is not clear how specific they are to impulsivity levels per se.

Many forms of *behavioral* measures of impulsivity have been used. One of the more commonly used behavioral measures in both clinical practice and research is the continuous performance task or CPT. In the CPT, subjects have to discriminate among stimuli and indicate their choices by a motor response (e.g., pressing one of two buttons). On these tasks, high impulsive subjects make significantly more errors of commission (responding when they should not have) than low impulsive subjects.

Environmental/social constructs are important in the study of impulsivity because many of the sociocultural cues for impulsive responding, which are acquired at various developmental stages, are learned unconsciously. This implicit learning process can provide the cues for unconscious impulsive acts. These are the cues which, for example, marketing experts capitalize on or which substance abuse patients respond to. Learned cues can become part of a pathological process, as observed, for example, in bulimia. A refrigerator door may become a cue to eat.

Cognitive cues in impulsivity are more difficult to study because cognition is always inferential in nature. Cognition is studied by relating biological and behavioral responses to certain cues or emotional states. However, there are some relatively "pure" cognitive indicators of impulsivity. It has been demonstrated that high impulsive subjects have difficulty, for example, in accurately judging time periods. Subjects with high levels of impulsivity judge time periods as shorter than do subjects with low levels. Thus, when a mother tells a hyperactive child to "wait a minute," his judgment of time will be shorter than that of a nonhyperactive child and his "minute" may be only 10 seconds in duration. These problems in time judgments have been related to "internal clocks" or rate of information processing.

Progress toward better understanding of impulsivity is being made through each of these emerging systems, as exemplified by models like the newly developed "social-cognitive-neurosciences." A discipline-neutral approach that synthesizes the cross-disciplinary substrates of impulsivity will eventually lead to a discipline-neutral definition of impulsivity as an impulsivity index to advance the study of causes and treatments of pathological impulsivity.

INDEPENDENT PRACTICE

Whereas psychologists are trained to conduct a wide variety of psychotherapeutic interventions of various styles and approaches, and to assess intellect, aptitude, personality, neuropsychological functioning, and marital adjustment, agency or institutional practice generally restricts the psychologist's practice to those elements required by the institution for which the psychologist works. In the independent practice setting, clinical psychologists tend to work autonomously. They have the opportunity to decide on the best utilization of their own skills and tools.

During the 1950s, there were perhaps 50 psychologists in full-time independent practice in the United States. As of 1995, at least 10,000 psychologists were in full-time independent practice. It is generally agreed that those who enter independent practice in clinical psychology should have the doctorate from an approved training institution, as well as 2 years of postdoctoral supervised experience in clinical psychology. Various states have licensing or certification requirements that represent the journeyman level of competence for independent practice.

Most psychologists committed to independent practice have found that it has considerable advantages. These include

1. The opportunity to offer a broad spectrum of psychological services.
2. The opportunity to develop services that the practitioner knows best, enjoys most, and delivers effectively.
3. The free choice and opportunity to avoid rendering partial, long-delayed, or inappropriate services.
4. Relative freedom from political and bureaucratic constraints and demands.
5. Fair compensation for extra skill, effort, or commitment.

6. The opportunity to become an experienced practicing clinician without loss of status or income.
7. The opportunity to pursue a broadening of skills and training without the constraints of institutional budgets.
8. The option of offering services to anyone without regard to eligibility.
9. The opportunity to make oneself available as a trainer of skill and experience.
10. The option of selecting surroundings, equipment, supporting staff, and the style of service delivery. Excellence and its pursuit is limited only by the practitioner's education, training, ethical constraints, and goodwill.
11. A clearer attribution of success or failure to the practitioner.
12. The opportunity to be the first and last person to see the consumer. Direct access increases the probability of delivery of competent service, more personal involvement, early resolution of misunderstandings, and better evaluation of benefit.
13. The freedom to adjust fees to the consumer's income.
14. Freedom from institutional constraints—real or symbolic.
15. Variety of activity and scheduling flexibility, which are likely to increase the quality of life for practicing professionals.

Surveys indicate that in American communities the range of saturation for full-time independent practitioners of psychology is from 1 per 2500 population to 1 per 135,000. Thus, this particular model for clinical psychologists offering direct consumer service may be the model of the future.

Theodore H. Blau

INDIVIDUAL DIFFERENCES

The communication system developed by humans not only makes them unique in regard to other animals, but also makes individuals unique in regard to one another. Speech and language require adequate physical and neural development and similar sensory experiences for humans to develop the basic skills required in communication. Genetic or physical damage to all or part of the nervous system, inadequate sensory development, or inadequate learning experiences can make individuals different. The age at which experiences occur, as well as emotional factors and opportunities, can contribute to individual uniqueness.

As a result of human uniqueness, psychology has had to turn to more general and less effective group approaches to try to gain information about the individual. Methods of evaluation and statistical techniques had to be developed to make the evaluation results useful. This has taken a great deal of time; as a result, the scientific investigation of individual differences, along with the special factors that exist in each case, is of relatively recent origin. It has become a specialized area within the general field of psychology known as differential psychology.

A major problem in differential psychology is the kind and number of ways an individual can be different. Differences start at conception as a result of the great differences in the chromosomes and genes available in each parent. There are the effects of environment on the selection of chromosomes and genes plus the physical, mental, and emotional state of the mother who carries the child-to-be. Other factors include the nutrition available during the developmental period and after birth, the amount of stimulation available after birth, the types of traumatic experiences that may occur, the others in the individuals' environment, and the kinds of educational experiences available.

The particular genes supplied by the parents are the determiners of the basic physical, mental, and emotional development of the individual. Each set of genes is unique, even in the case of identical twins. Recent studies have found maternal environmental differences that can affect the development of one twin more than they affect the other.

The environment can only modify what is already present. For example, failure to supply something that is needed, such as vitamins or proteins, or the presence of harmful physical or chemical factors can make dramatic changes.

Stimulation is necessary for the normal development of an individual. Sensory deprivation can lead to retardation in motor and mental development.

Traumatic experiences in the form of shocks or insults can create individual differences. A fall in which the head or neck is damaged can affect physical, mental, and emotional development. Emotional experiences of a traumatic nature can have a short-term or long-term effect on intellectual development. A devastating illness can leave physical, mental, and emotional damage in its wake.

Sexual differences are observable after birth. Girls tend to develop faster than boys, and this will affect brain development. Early developers have better verbal than spatial abilities, whereas late developers perform better on spatial than on verbal tasks.

In the area of physical growth a relatively orderly sequence of development exists, primarily based on inheritance. Although the order is relatively the same from child to child, the rate of development can vary tremendously, with some infants reaching the stage of standing or walking months ahead of others. Sex differences play a primary role here: By 5 years of age, girls tend to be 4 months or more ahead of boys. Major differences between the sexes can be seen in the preadolescent growth spurt that occurs

toward the end of the childhood period, beginning 2 years before adolescence. The average girl begins her growth spurt shortly after age 10 and achieves adolescence by approximately 12.5 years, with a deceleration of growth by age 14. The average boy begins his growth spurt at about 13 years and achieves adolescence around age 15, with a deceleration of growth after 16.

Learning experiences play such an important part in emotional development that no clear-cut differences in emotional behavior have been found for the two sexes. As a child matures, the emotional characteristics undergo major changes and the type of experiences that generate emotional reactions also changes. Parental attitudes and behavior, the culture, and the environment are all important factors in an individual's emotional development, but so are the individual's own characteristics.

Francis Galton is given credit for the first systematic investigation of individual differences. Convinced that heredity was the major factor in differences among people, he devised a sensory–motor test that discriminated among stimuli. This test has been called the first measure of intellectual potential.

James M. Cattell was interested in the differences between individuals in several areas including academic success. He is said to have used the term "mental test" as early as 1890.

Alfred Binet became interested in individual differences as a result of his work with hypnosis and his observations of the different ways his daughters solved problems. Working with Theodore Simon, he developed the first real intelligence scale in 1905 when he assembled a group of cognitive and sensory tasks in an attempt to identify retarded children in the French school system.

Testing materials and approaches have greatly improved. New techniques for evaluating testing materials and their results have increased the usefulness of these devices. As a result, it is easier today to determine an individual's strengths and weaknesses and then to place that individual in the best existing educational or training program designed to meet his or her needs.

Measurement is the only way that has been found to determine how one person will differ from another in ways that cannot be directly observed. Intellectual functioning is the area most frequently involved in controversy over devices used for measuring individual differences. An individual's intellectual functioning depends on the inherited potential plus an environment that permits the development of that potential. But IQ is not a constant characteristics such as eye color. If IQ scores are accumulated on the same individual over a period of time, there is an increase in the constancy of the scores. This improvement in constancy can be related to the changes that occur as the result of maturation, plus the experiences that improve the individual's ability to deal with information in the nervous system. In addition, learning experiences over a period of time fill in some of the earlier gaps in knowledge until some degree of balance is reached and the scores become more and more alike.

There are many aspects of intelligence not adequately dealt with on an IQ test, which tends to concentrate on abilities most relevant to school learning. An accurate picture of intelligence requires the sampling of performance in a broad range of abilities. The scores obtained reflect experiences that have taken place in and out of educational institutions interwoven with psychological factors pertinent to the particular individual.

No matter what test is used to measure individual differences, there are always additional factors to be considered, such as the individual's physical, mental, and emotional state at the time of the examination; the ability of the individual to understand the directions or to use the materials effectively; the time of day, week, or month; the area used for testing; the temperature; the amount of light available; and the amount of noise in the background. Any one of these things and many more can affect the score of a particular individual on a particular day.

INDIVIDUALISM

In common usage, *individualism* is defined as leading one's life in one's own way without regard for others. Individualism may be separated from *individuality,* which is the sum of the qualities that set one person apart from others. To *individualize* is to distinguish a person as different from others, whereas to *individuate* is to make a person individual or distinct. Individualism is also distinct from *autonomy,* which is the ability to understand what others expect in any given situation and what one's values are, and to be free to choose how to behave based on either or both. While individuality and autonomy are important aspects of healthy psychological development and health, individualism is not.

Based on the theorizing of Morton Deutsch (1962) and David Johnson and Roger Johnson (1989), individualism may be defined as believing and behaving as if one's efforts and goal attainments are unrelated to or independent of the efforts toward goal attainment of others. Individualism is usually contrasted with cooperativeness and competitiveness. *Cooperativeness* may be defined as believing and behaving as if one's efforts and goal attainments are positively related to the efforts and goal attainments of others, or as if one can achieve one's goals if, and only if, the others with whom one is cooperatively linked obtain their goals. *Competitiveness* may be defined as believing and behaving as if one's efforts and goal attainments are negatively re-

lated to the efforts and goal attainments of others, or as if one can achieve one's goals if, and only if, the others with whom one is competitively linked fail to achieve their goals.

There is considerable research comparing the relative effects of individualism, cooperativeness, and competitiveness. These reviews have primarily been conducted by David Johnson and Roger Johnson and their colleagues (Johnson & Johnson, 1989, 1999). Individualism, compared with cooperativeness, tends to be related to: (1) lower beliefs that one is liked, accepted, supported, and assisted by others; (2) less seeking of information from others, and utilizing it for one's own benefit; (3) lower achievement, intrinsic, and continuing motivation, and greater orientation toward extrinsic rewards; (4) less emotional involvement in efforts to achieve one's goals; (5) lower achievement; (6) lower ability to take the cognitive and affective perspective of others; (7) less healthy processes for deriving conclusions about one's self-worth; (8) lower psychological health, as reflected in greater psychological pathology, delinquency, emotional immaturity, social maladjustment, self-alienation, self-rejection, lack of social participation, basic distrust of other people, pessimism, and inability to resolve conflicts between self-perceptions and adverse information about oneself; and (9) less liking for others and more negative interpersonal relationships. There has been very little research comparing individualism and competitiveness.

If the direct evidence is not very favorable toward individualism, the writings in personality and clinical psychology are even less so. The solitary human who avoids relationships and coalitions with others is considered abnormal. Humans are basically interdependent beings, biologically and socially. Effective socialization brings with it an awareness that one cannot achieve one's life goals alone; one needs other people's help and resources. Psychological health requires a realization that one's goals and the goals of others, one's efforts and the efforts of others, and one's success and the success of many different people, are all related and interdependent. Accurately perceiving the interdependence between yourself and others involves an awareness of sharing a common fate (both you and your fellow collaborators will receive the same outcome); a recognition of mutual causation (achieving your goals depends on both your own efforts and those of collaborators); the possession of a long-term time perspective; and an appreciation of the skills, information, competencies, and talents of other people as well as oneself. Individuals high on individualism do not have a high degree of these traits. Individualism often brings with it the following: (1) feelings of alienation, loneliness, isolation, inferiority, worthlessness, depression, and defeat; (2) attitudes reflecting low self-esteem, an emphasis on short-term gratification, and the conviction that no one cares about one or one's capabilities; and (3) relationships characterized by impulsiveness, fragmentation, withdrawal, and insensitivity to one's own and others' needs.

Every person needs to establish a coherent and integrated identity that differentiates him or her as a unique individual, separate and distinct from all others. While the ability to act independently, autonomy, and individuality are all important aspects of developing an identity, individualism is not. Paradoxically, it is from collaborative and supportive relationships that encourage individuality that a mature identity is formed. Self-awareness, self-understanding, differentiating oneself from others, the internalization of values and self-approval, and social sensitivity are all acquired through encouraging and cooperative relationships, not through isolation or leading one's life in one's own way without regard for others.

INDUSTRIAL–ORGANIZATIONAL PSYCHOLOGY

That branch of psychology concerned with the scientific study of behavior in the workplace and/or the application of psychological knowledge to that setting is known as industrial–organizational psychology. The field stresses both knowledge generation (research) and the application of that knowledge (practice) to better meet the needs of employees and employers.

Industrial–organizational psychology represents the merging of two disciplines of psychology to address behaviors in the workplace. One discipline is individual differences. Psychologists well grounded in the understanding of human abilities brought this knowledge to the workplace and focused upon the match of job demands with individual skills and abilities. The second focus flows from social psychology. This focus, best expressed by Kurt Lewin, is concerned with the attitudes and behaviors of people in social settings encountered in the workplace. At one time industrial psychology referred to the first focus, and organi-

zational psychology to the second. Today the single discipline represents the merger of the two.

Selection and Placement

One of the most important concerns of industrial–organizational psychologists is that of selecting individuals to fill the various work roles in an organization, and placing the employees hired by the organization in jobs so as to create a good match of people to jobs. To accomplish these selection and placement tasks, the following procedures represent major concerns of industrial psychologists.

Job Analysis

A job analysis is the study of the job requirements. It first involves a description of the duties and responsibilities of the person who holds the job. In addition, the job analysis goes beyond the simple description of what must be done to suggest the human characteristics necessary to accomplish the job successfully. It is absolutely necessary that the nature of the job be understood before any attempt is made to select or place persons in the job. In addition to selection, job analyses are also essential for developing compensation systems and guiding career development and training programs. The nature of jobs and their links to many job functions have been greatly facilitated by the recent development of the Occupational Information Network (O*NET), a national database of jobs and job characteristics.

Personnel Assessment

Once the job characteristics have been assessed, it is necessary to assess the characteristics of individuals so as to match persons with jobs. The industrial–organizational psychologist must choose methods for assessing job-relevant individual characteristics that (1) are appropriate for the characteristic being assessed, and (2) possess acceptable psychometric properties of reliability and validity. Since standardized tests of skills and abilities, aptitudes, and/or interests often provide the best means of accomplishing these two objectives, the industrial–organizational psychologist must have a thorough knowledge of the standardized tests available and how to construct and evaluate tests. Situational interviews, assessment centers, biographical data, and a variety of other standardized measures are used to measure individual differences. Finally, it is the professional, ethical, and legal responsibility of the industrial psychologist to develop assessment procedures that are reliable and valid and do not discriminate unfairly against particular groups.

Criterion Development

Once employees are on the job, ways of assessing their effectiveness must be developed. This task encompasses the classical criterion problem that has received considerable attention from industrial psychologists. The development of criteria first involves identifying those job behaviors or outcomes relevant to effective job-role accomplishment, and then developing ways to assess validly and reliably the dimensions identified.

Validation

The final step in the selection and placement process is to evaluate the fit between individual characteristics used for selection and the effectiveness of these individuals on the job. This complex process is referred to as validation or the validity study.

Performance Appraisal

Judgments about the effectiveness of employees' job performance often must be based on subjective evaluations obtained from other individuals. Although these judgments can be made by any of a number of individuals on the job, the task of judging employees' performance is usually accomplished by their immediate supervisors. These evaluations serve a wide variety of functions. Performance evaluations can be used as criteria for validating selection systems. They are also used for determining raises and promotions, to evaluate training effectiveness, and to counsel employees about their performance on the job or their long-term career goals. Subordinates, peers, and supervisors often provide feedback in order to provide employees with information about how their work and interactions are seen from many perspectives. Providing supervisors with appraisals from multiple sources for developmental purposes is currently referred to as 360-degree feedback.

The establishment of appraisal systems requires that rating scales and procedures for using them be developed so that the ratings are as unbiased and accurate as possible. To accomplish this, researchers are faced with complex issues of scale development and policies for conducting such ratings. Major advances have been made in this area. One of the most important involves scaling critical job behaviors and describing them in the job incumbent's own words.

Training

When employees or potential employees do not possess the knowledge, skills, or abilities needed to perform their jobs, they may obtain knowledge and skills through training. Industrial psychologists are involved in all four of the major phases of training. The first phase is a needs analysis, which considers the present and near-future demands of the jobs in the organization and then, in a very real sense, inventories the extent to which the workforce possesses the knowledge and skills that are and will be needed. This analysis considers not only the present employees, but also es-

timates the losses of personnel through retirement and other forms of turnover during the time period of interest. Once the needs analysis is complete, the industrial psychologist plans training programs to meet these needs. During this second phase, the psychologist applies what is known about human learning and training methods to best facilitate the development of the knowledge and skills needed.

The third phase of the training process is the actual training. Industrial psychologists frequently are involved with conducting training. The ability to deliver training over the Internet, to create relatively high fidelity simulations with computers, and to make use of other recent advances are rapidly changing the nature of training. Finally, the effectiveness of the training should be assessed. It is the responsibility of industrial–organizational psychologists to attempt to build into the conduct of training programs ways to assess their effectiveness.

Work Motivation

The industrial–organizational psychologist deals with motivation at three different levels. First of all, psychologists must have a thorough knowledge of human motivation in general. They need to be aware of current theory and thinking related to motivation, regardless of the setting. At a more work-related level, at least four general motivationally-oriented processes are applied by the industrial psychologist. These are incentive systems, goal setting, participation in decision making, and job design. Incentive systems development involves the association of valued rewards with behaviors that the employer wants to encourage. To use incentives effectively requires a thorough knowledge of what is valued by employees and the likely behavioral effects of making valued outcomes contingent upon performance. In addition, one must be aware of the relative value of the incentives in the marketplace. Goal setting involves the establishment of standards for performance and feedback with respect to those standards. Participation in decision making or autonomy is predicated on the assumption that employees desire to have more say in what goes on at work. Industrial–organizational psychologists often have attempted to build participation into managerial/leadership training, performance appraisal, and other processes in work settings. The success of these procedures has been mixed. To a large extent, it depends on whether one is interested in improving performance or increasing employee satisfaction.

Motivation is affected by having jobs designed so that job incumbents can believe their needs can best be met by behaving in a way that meets the organization's goals. The design of motivationally-focused systems tailors the general motivational strategies to the particular organizational setting, its culture, and its employees. To do this, some combination of the four motivational processes just described is typically used. Increasingly, job design incorporates multiple employees in teams and work groups, where motivation is focused not only on individual task performance but also on the coordination and maintenance of effectively functioning teams.

Job Satisfaction

A great deal of effort has been expended by industrial–organizational psychologists to assess work attitudes. In particular, there is considerable interest in measuring employees' satisfaction with their jobs. Much of the earlier work was motivated by the assumption that the more satisfied people were with their work, the more productive they would be. In the face of repeated failures to show that this was true, later work with job satisfaction has stressed the value of a satisfied work force as an end in itself. Also, information about satisfaction has a great deal of diagnostic potential for the organization. With it, the organization can often identify problem areas and then take action to alleviate these problems.

Job satisfaction measures are most useful when they are a part of a regularly scheduled attitude survey repeated over time in the same organization. Periodic surveys provide feedback from employees on a regular basis, helping to identify trends in changes in attitudes and providing information for supervisors about the feelings of the people who work for them. Such surveys are also frequently used to assess the reactions of customers.

Job Design

Although job design has been mentioned briefly under work motivation, more space needs to be devoted to it, because of its relevance to industrial–organizational psychologists from a broader perspective than motivation. In particular, jobs must be designed to fit the abilities of the individuals who hold the jobs, as well as their motivation. Therefore, industrial–organizational psychologists tend to take one of two general approaches to job design. One is a motivational approach. Recent motivational emphasis has been on changing jobs so that they allow job incumbents more control, autonomy, feedback, and opportunity to be involved in their work. This point of view underlies the area known as job enrichment. With the increasing use of teams in the work setting, job design is also being raised to a level above that of the individual to include coordination, cooperation, helping, and other interpersonal behaviors.

The other orientation toward job design concentrates on individual abilities and attempts to design tasks in jobs to match, as closely as possible, the abilities of the jobholders. This field is known as human factors engineering or ergonomics. This field has been strongly influenced by the information processing capabilities of human beings and machines with respect to the interface between people and computers, and influenced also by the technological advances in robotics. As a result, the field of human factors

has become a subset less of industrial psychology than of applied experimental psychology and/or industrial engineering.

INFERIORITY FEELINGS

Alfred Adler distinguished between inferiority feelings and inferiority complex. Adler assumed a feeling of inferiority on the part of everyone. He pointed out that to be human means to feel inferior. Inferiority feelings were traced to the child's smallness and dependence in a world of adults, and later to the pursuit of perfection.

Feelings of inferiority may serve as a stimulant to healthy, normal striving and development. They become a pathological condition only when the individual is overwhelmed and becomes depressed and incapable of development. Orgler states that Adler found that inferiority complexes can develop from three sources: organ inferiority, spoiling, and neglect. When feelings of inferiority result in avoiding participation in the community, they become a complex.

The word *inferiority* is derived from the Latin *inferus,* meaning "below" or "under." Whenever a person feels inferior, it implies comparison with another person or some standard or norm. Such comparisons are the starting point of much human misery. Next, a host of other negative factors occur, including anger, competitiveness, and a consequent loss of initiative because competition, by focusing one's efforts on a rival, precludes spontaneity. Furthermore, one may act in a superior manner: A superiority complex can compensate for an inferiority complex.

To conquer the feeling of inferiority, two things must be done. First, one must stop comparing oneself to another so as to give full and undivided attention to the problem or task at hand. Second, one must surrender the need to be superior. Renouncing the need for superiority and privilege, one finds one's balance, gains momentum, and ceases to feel inferior.

Inferior self-assessment is always a negative thing, yet sometimes it serves as a stimulus for constructive and useful compensation. Out of weakness and deficiency can grow strength. In such a situation it is not inferiority itself that is advantageous, but the constructive overcoming of weakness and deficiency.

Related to inferiority feelings are feelings of inadequacy. Whereas inferiority implies feeling not as good as someone else, the inadequate person feels unable to cope with tasks. The frame of reference is not another person but the task one cannot handle. Just as, according to Adler, one overcomes inferiority feelings by giving up comparisons and the desire to be superior, so, to overcome inadequacy, one must focus on the task at hand and have the courage to be imperfect.

INFORMED CONSENT

Informed consent is the ethical and legal obligation psychologists have to obtain consent from persons prior to conducting assessment, treatment, or research. The doctrine of informed consent requires persons to be informed of potential benefits and risks of the contemplated procedures, as well as any possible alternative procedures. Underlying the informed consent doctrine is the principle that allowing individuals to make informed decisions respects each person's autonomy and self-determination.

Three Elements of Consent

Valid consent implies that participation in assessment, treatment, or research is given intelligently, knowingly, and voluntarily. Intelligence, sometimes referred to as competency, is defined as the capacity to comprehend and evaluate specific information that is offered. Psychologists should follow the reasonable patient standard in deciding what information to provide. This standard imparts an affirmative duty on professionals to give as much information as a reasonable patient would desire to make treatment decisions. At a minimum, the following information should be provided to assure informed consent: purpose of the procedure, any potential risks and benefits, alternative procedures available, limits of confidentiality (e.g., mandated reporting of child abuse), general client rights (e.g., the right to withdraw from therapy at any time), qualifications of the professional, and logistical information (e.g., scheduling practices, fee structures, emergency procedures).

Providing required information alone is necessary but not sufficient. In addition, consent must be given knowingly or with appreciation. In order to ensure that a person fully appreciates the information provided, psychologists must regularly question comprehension of the material. One way of assessing comprehension is to ask the person to repeat, in his or her own words, information on the procedure that was presented previously. Finally, the voluntary element of informed consent suggests that such consent may not be coerced or enticed by the professional. For example, psychologists should avoid promising miraculous and timely cures; they should also avoid offering financial incentives for participating in treatment or research studies.

Bases of Informed Consent

Legal Bases

Several legal cases illustrate the importance of obtaining informed consent for treatment (e.g., *Mohr v. Williams,* 1905; *Schloendorff v. the Society of New York Hospital,* 1914; *Canterbury v. Spence,* 1972). Repeatedly, courts have found in favor of patients' being apprised of all relevant information regarding treatment. Failure to do so may constitute battery or assault, and the psychologist may be held legally liable for any damage that results.

In research contexts, federal regulations promulgated by the Department of Health and Human Services legally require psychologists to obtain valid consent prior to initiation of a study. However, in treatment settings, there are no federal or nationwide statutes on informed consent for psychological interventions. Although all states have statutes mandating some type of informed consent procedures for physicians and psychiatrists, not every state specifies that psychologists or other mental health providers must obtain informed consent for psychological treatments. It is incumbent on treating clinicians to be aware of the statutes in the states in which they practice, as laws regarding informed consent for therapy vary across state lines.

Ethical Standards

Ethical codes of conduct clearly dictate that psychologists apply the concept of informed consent in both treatment and research settings. For example, the ethical codes developed by the American Psychological Association (APA) and the American Counseling Association (ACA) both contain sections dealing with informed consent for clinical interventions and research studies. The overarching principles espoused in these ethical codes is that professionals must consider each person's best interests, autonomy, and self-determination.

Research on Informed Consent

Informed consent typically is documented in writing by having the person sign a consent form. There has been little research conducted on the process or effects of utilizing written consent forms. Studies have found that the average length of such forms doubled from 1975 to 1982 and that these forms generally require the reader to have at least a college education in order to comprehend and appreciate the information. Unfortunately, researchers also have found that longer consent forms inhibit the amount of information retained. It appears clear that clients and research participants often agree to engage in procedures that they do not fully understand, which belies the whole idea of informed consent.

Regarding children, only adults are considered able to understand procedural information and to be legally competent to give consent. Therefore, in many states, consent to assess, treat, or study minors must be obtained from a legal guardian or parent. However, some state statutes give minors limited rights to consent to treatment, in particular. Regardless of state law, it is important to involve even young children in the process of obtaining consent, as researchers have found that even young children (i.e., age 7 or above) may be capable of understanding and weighing options.

Several studies have examined the effects of written consent forms on the therapy process. In general, the literature has documented primarily positive results from the use of written informed consent forms. For example, researchers found that the use of more written information increased participants' positive judgments of therapists' experience, likeability, and trustworthiness, particularly with respect to less experienced therapists. In addition, researchers have found that written consent forms do not negatively affect client attendance, nor do they increase the likelihood of premature termination. Despite these promising findings, research has been mixed on the impact of written consent forms on client disclosures in treatment settings. Some studies have found that warning clients of the limits of confidentiality reduces client disclosures, whereas other studies have found that it has no impact. Due to conflicting findings in the literature, further research is needed to clarify the impact of informed consent procedures on client disclosures in treatment settings.

INHIBITORY CONDITIONING

At the beginning of the twentieth century, Ivan Pavlov developed the original model of conditioning. In his research, he conditioned dogs to salivate at the sound of a bell by the repeated process of ringing the bell and then presenting food. His research showed that each time the bell and food were paired, the amount of saliva that the dog produced increased. Using the standard terminology, the bell is referred to as the conditioned stimulus (CS), the food is the unconditioned stimulus (US), the salivation in response to the ringing of the bell is called the conditioned response (CR), and each bell–food pairing is called a trial. In this study, Pavlov was interested in the processes that cause the CS to activate or "excite" the behavior of salivation. In this example, the CS is referred to as "excitatory" because it acts

to elicit the CR. However, Pavlov was also interested in the processes that are responsible for the "inhibition" of responding. In inhibitory conditioning, the CS acts against the elicitation of a conditioned response.

The standard conditioned inhibition procedure involves two phases. In the first phase, a CS such as a tone is repeatedly paired with the presentation of a food US (T+ trials), until the subject shows a stable salivary response to the tone. As in the previous example, the tone can be considered excitatory because it elicits the CR of salivation. In the second phase of the procedure, two types of learning trials are randomly intermixed throughout the phase. One trial type is the same as that given in the first phase (T+ trials). The second trial type involves the simultaneous presentation of the tone and a second stimulus, such as a light. However, on these compound trials, no food is given (TL– trials). At the beginning of this phase, the dog may salivate on both the T+ trials and the TL– trials. However, as the phase progresses, the dog will eventually stop salivating during the presentation of the compound stimulus, TL, while continuing to salivate during the presentation of the tone alone. Thus, the light may be considered inhibitory because it appears to act against the elicitation of a CR that would have normally been produced by the tone.

Although Pavlov discovered conditioned inhibition in the early 1900s, inhibitory conditioning did not command the serious attention of researchers until over 40 years later when Rescorla (1969) reintroduced the topic by arguing that the candidate inhibitor must pass a both a "summation test" and a "retardation test" in order to be declared a true conditioned inhibitor. For the summation test, a third stimulus is employed. This new stimulus (say, a bell) has already been paired with a US, and is thus known to be excitatory. During the test, the candidate inhibitor (L) is presented in compound with the bell (BL– trials). The light is said to pass the summation test if it is successful in reducing the level of conditioned responding to the bell. In the retardation test, the candidate inhibitor (L) is paired with a US (L+ trials) and the rate at which the light acquires excitatory strength is observed (as measured by the development of conditioned responding). It is said to pass the retardation test if it acquires that strength more slowly than would a neutral or novel stimulus paired with the same US.

Rescorla maintained that a candidate inhibitor must pass both of these tests because a CS could pass either one of these tests alone and still not be a true conditioned inhibitor. For example, if it had only passed the summation test, one could argue that it was merely distracting the animal and drawing the animal's attention away from the excitatory stimulus. If it had only passed the retardation test, then one could argue that the training during the second phase served merely to cause the animal to ignore the stimulus. However, if it passed both tests, neither the "distracting" nor the "ignoring" explanation could work—a stimulus cannot be both distracting and ignored at the same time; it must be a true conditioned inhibitor with the ability to act against the elicitation of a conditioned response.

Rescorla's belief that a conditioned inhibitor must be able to pass these two special tests reflects the concept that excitation and inhibition lie at opposite ends of a single continuum of associative strength. Excitation and inhibition were viewed by Rescorla and others as opposing associative processes that carried opposite signs and counteracted each other (Rescorla & Wagner, 1972). The summation and retardation tests were meant to capitalize on this opposition by pitting the two opposing processes against each other. However, some studies have suggested, and some theories argue, that inhibition is not the symmetric opposite of excitation and that they are not two mutually exclusive associative processes (Matzel, Gladstein, & Miller, 1988; Williams & Overmier, 1988; Zimmer-Hart & Rescorla, 1974). Some researchers have rebelled against the notion of inhibition itself, suggesting that what appear to be the effects of inhibition on conditioned responding are really the effects of varying amounts of excitation in combination with some principle of performance (Gibbon & Balsam, 1981; Miller & Schachtman, 1985). These theories explain the behavioral effect of a putative inhibitory CS in terms of a comparison of the CSs' relative strengths of excitation. For a review of this issue, see Williams, Overmier, and LoLordo (1992).

INNER/OUTER-DIRECTED BEHAVIOR

The problem of internal as compared to external control concerns, first, the circumstances under which one perceives one's own behavior to be determined by forces in the environment or by oneself. Second, it concerns the possibility that even in the same situation, people differ in the processes that govern their own behavior.

Almost any line of research points to the influence of cognitive factors in the selection and control of response. The Würzburg school showed how instructions or task conditions induce in the subject a *set* or particular kind of readiness to respond, which then determines subsequent responses. Following the lead of E. C. Tolman, many psychologists employ the term *expectancy* for this phenomenon. Even more generally, the term *attitude* refers to the regulative function in personality.

A set is essentially defined by experimental conditions and is inferred by effects associated with variations in those conditions. But an attitude requires measurement independent of the situation, such as by a personality test. When differences appear in performance, then, we would link them with intrinsic variations in cognitive structure.

It is usually not sufficient just to assess a personality variable. Its mere presence in the subject does not guarantee that it will influence response. For this reason, an experimenter needs to include conditions that maximize its operation. These conditions include *arousal* or *induction* aimed at the variable in question, and a task that engages the subject's *interest* or commitment enough to involve his or her resources.

Research on internal—as compared to external—control of behavior has employed strategies, on the one hand, of manipulating cognition by extrinsically imposed conditions, and on the other hand, by identifying groups who differ in antecedent assessment of these inferred characteristics. The former approach has to do with sets or expectancies, the latter with attitudes. In neither strategy have the requisite conditions just mentioned always been fully recognized.

Expectancies of Control

Interest in the problem of personal control owes much to research on frustration and its effects—situations in which a person is blocked in attempting to attain a goal. Emotional arousal and aggression may thereby be elicited (although negative effects are typically emphasized, constructive or coping efforts may also be evident). Such reactions vary with the degree of control one has over the threatening conditions. For example, with a threat of electric shock, subjects prefer certainty that the shock will occur to uncertainty or inconsistency, and report less anxiety when they control the shock lever. Other studies bear out the fact that perception of control of aversive stimuli significantly reduces subjective discomfort. Even an illusion of control can influence one's reactions to a situation. The "self-fulfilling prophecy" is another interesting phenomenon in which an expectation about what will happen influences one's behavior. Archibald has reviewed possible interpretations of such effects. An expectation of failure may arouse anxiety so that a person tries to alleviate such feelings, or the aroused state may produce inappropriate effort (trying too hard or paying attention to the wrong cues). Alternatively, an expectation of a favorable outcome may simply increase effort and thereby facilitate performance. A person highly involved in a task may be oriented primarily to preserve self-esteem or some important value. Therefore, the task or goal may be redefined to avoid disconfirmation of the expectation. Thus if one expects to fail, the task may be perceived as too difficult, with an adverse effect on performance. Clearly, no explanation fits all cases.

Reactance

Brehm and others presented a systematic analysis of what occurs when the environment imposes restrictions on a person's freedom to act. Such conditions, Brehm argued, induce arousal, which makes a person act to prevent a further loss of freedom and to reestablish the diminished or threatened freedom. This counterforce he calls "reactance." Experiments have confirmed predictions from this theory.

Origin–Pawn Orientations

De Charms extended Heider's causality proposition. An Origin feels that environmental effects are produced by oneself and thus has a sense of competence and control. A Pawn perceives that events are caused independently of one's actions and thus feels powerless or ineffectual.

Locus of Control

Rotter devised a test for a related attitude. It is conceptualized as general beliefs concerning the relationship between one's own actions and events. *Internal control* is the belief that an event is contingent on one's own characteristics or acts. *External control* is the perception that one's behavior is controlled by forces beyond (or mostly beyond) one's control, such as fate or luck. This distinction has been made by other social scientists as well, such as Fromm and Riesman.

The Internal–External Control Scale gets at one aspect of the expectancy component. The subject is asked to choose between pairs of statements, and the score is the number of "external control" alternatives chosen (thus a low score reflects internal control). For example, in one item there is a choice between making plans confidently and reluctance to do so for fear that bad luck may foil them.

This scale has prompted a great deal of research as well as the development of new measures. Several investigators have employed factor analysis to clarify the components of

the scale. In particular one needs to distinguish, as aspects of the external locus, between control by powerful others and control by chance, and between defensive and nondefensive externals. Nondefensive externals assume more personal responsibility for their actions than do defensive externals.

Research shows that internals tend to perceive themselves as capable of controlling events, whereas externals tend to attribute outcomes to luck, chance, or other forces that control them. In general, internals are more confident than externals.

Learned Helplessness

Seligman developed the notion of learned helplessness, which may ensue when one experiences outcomes that occur independently of one's activity (i.e., are uncontrollable). Hiroto and Seligman exposed subjects to an aversive noise or to a concept task. Some of them could "escape" the noise by pressing a button that terminated it. For some subjects the concept problems were unsolvable, whereas for others they were solvable. Control subjects merely listened to the noise or inspected the problems. Next, the subjects either experienced the same conditions again (albeit with instructions that they could do something to escape) or received anagrams to solve the problem. The subjects who received "helplessness training" (inescapable noise or unsolvable problems) displayed learned helplessness in that they were impaired in learning how to escape the noise or solve the anagrams (depending on which sequence they encountered).

Clearly, the attitude of the person ought to influence how a task is treated. Hiroto utilized a test derived from the Rotter scale in an experiment on learned helplessness. One set of instructions emphasized skill; the other emphasized chance. The "no escape" pretreatment produced helplessness effects. But externals were adversely affected regardless of pretreatment or instructions; in fact, internals performed very much like the control subjects. In the helplessness training pretreatment, internals tried more often to escape than did externals. Zuroff has also shown that the effects of helplessness training are to be understood as a function of the subject's expectancies, whether sets or attitudes. In addition, as Koller and Kaplan, and Gregory and colleagues show, it is the lack of explicit cues that adversely affects the performance of externals, in keeping with their greater influence by environmental conditions.

Locus of Control and Reactance

The effects of extrinsically imposed conditions clearly vary as a function of personality characteristics. The interaction between internal–external control and the induction of reactance appears in a study by Cherulnik and Citrin. Subjects rated four attractive posters and were promised a choice of one of them as a reward. However, in a second session, when new ratings were obtained, the poster rated as third highest (identified separately for each subject) was not available. Some students were given *impersonal* instructions (that the shipment of posters inadvertently failed to include that poster); others were given *personal* instructions (that the experimenters had excluded one because evidence indicated that it would not be "meaningful for that student"). A control group merely made the two ratings. When freedom was limited, internals rated the eliminated option much more attractive under *personal* conditions, whereas the externals displayed this effect under *impersonal* conditions. Although restrictions on freedom may have general effects, they are contingent on relevant personality variables.

Perceptions of Causality

Research on attribution processes stemming from conceptualizing by Heider, and on expectancies associated with achievement motivation, converge on the locus of control variable. Theories of achievement motivation and internal–external control share some common features.

Accordingly, Weiner and associates have presented a systematic picture of how internals and externals perceive their performance. Internals tend to attribute their success or failure to their own characteristics—ability and effort—whereas externals attribute their outcomes to factors outside themselves—difficulty or luck. Several studies support this distinction.

Persons high in achievement are especially likely to attribute success to ability and effort, which increases feelings of accomplishment. When failure occurs, the outcome is attributed to lack of effort, which, as an unstable condition, can be increased. These persons prefer tasks of intermediate difficulty in which difficulty can be countered by increased effort to enhance the likelihood of success. They act vigorously because they believe that effort leads to success, and tasks of intermediate difficulty are most likely to benefit from effort.

In contrast, persons low in achievement avoid achievement-related activities because they attribute success to external factors, and effort is not considered to affect the outcome significantly. They give up when failure threatens because they believe that it results from a lack of ability (a stable and uncontrollable factor). These persons prefer easy or difficult tasks, which minimize self-evaluation.

W. E. Vinacke

INSTINCT

The concept of instinct is a very old one, going back to antiquity and the writings of philosophers who were inter-

ested in the natural behavior and psychology of animals, including humans. When an act, perception, motive, or goal is said to be instinctive, that means the observer views it as being unlearned and caused by the organism's hereditary make-up. Instincts are often adaptive, in the sense that they aid in the survival of the individual and the species (courting, mating, nestbuilding, and rearing of young in birds, for example). In the early part of the twentieth century, as psychology was struggling to become a recognized science, so many different instincts were attributed to humans that the concept was thought to be unwieldy, and so lost favor in some quarters. Another, more important criticism of the concept of instinct was its antianalytic flavor. If a behavior or perception was labeled instinctive, there was no reason to experimentally analyze its development in the individual because it was thought to come directly from the genes (genes → species-typical behavior). As it became clearer that the genes must influence behavior through the nervous system, the developmental understanding of instinct became genes → nervous system → behavior.

Beginning in the 1920s and 1930s, the popularity of the instinct concept waned in psychology, especially as the behaviorist school of thinking became dominant and much of behavior, perception, and motivation were thought to be learned or acquired rather than innate or instinctive. In the 1920s and 1930s, a small group of zoologists called ethologists became interested in the natural behavior of animals as observed in field settings, and they brought the instinct concept back into the scientific study of animals' perceptions, motives, and actions. They invented a whole new vocabulary for dealing with instinctive behavior: *Releasers* or *sign stimuli* were behavioral or anatomical features of other members of the species that innately triggered *fixed action patterns* (FAPS) that arose from special places in the nervous system that had been put there by genes. The motivational part was seen in the observation that, if the FAPs were not released by encountering the appropriate releaser, they would "go off in a vacuum" (i.e., without being triggered by a sign stimulus). Since the ethologists were zoologists who were trained in the importance of natural selection in the evolution of species, they focused on the reproductive behavior of species, especially birds. They found that each species had their own special set of releasers and innate motor movements (FAPs), and the more closely related the species, the greater the similarity in their releasers and FAPs. In the hands of ethologists, the classical features of instinct were defined as

1. species-typical or species-specific behaviors;
2. not dependent on known forms of learning;
3. adaptive (having survival value);
4. responsive to a narrow range of sensory stimulation (sign stimuli or releasers) provided by other members of the species and not requiring prior exposure to such stimulation;
5. largely or totally unmodifiable by the organism's experience;
6. attributable to hereditary influences operating directly on the nervous system to prepare the animal to behave in an adaptive fashion.

This was an imposing and precise list of defining features of instinct that motivated young, experimentally oriented animal behaviorists (both zoologists and psychologists) to analyze instinctive behavior under laboratory conditions. What was learned is that behavior, perception, and motivation, thought to be instinctive in the strict sense defined above, were more influenced by an animal's prior experience than previously believed to be the case. For example, in the instance of gulls rearing their baby chicks, the chicks come to peck (FAP) at a spot (releaser) on the lower mandible of the parent and the parent regurgitates predigested food that the young eat. In studies by Jack Hailman, it was found that the baby chicks are at first not accurate in their pecking response and only become so during a fairly protracted period of "practice."

In studying the motor patterns involved in courtship displays in various species, George Barlow and others observed significant individual variability in the precision of the motor patterns within every species studied (thus, the *fixed* action pattern became the *modal* action pattern). Moreover, in studying the instinctive perceptual response of newly hatched ducklings to the maternal assembly call of their own species, Gilbert Gottlieb found that in order for the ducklings' response to be species-specific, they had to have heard their own embryonic vocalizations. In the experimental cases in which the embryos were prevented from hearing their own vocalizations, the specificity of the posthatching response to the species maternal call was lost; they were as likely to respond to the maternal call of another species as they were to their own.

In a similar vein, David B. Miller found that the specificity of newly hatched ducklings' freezing response to the maternal alarm call was lost in the absence of their usual embryonic and postnatal experiences. In another remarkable case of a nonobvious prior experience preparing the developing animal to respond adaptively, Joshua Wallman found that preventing newly hatched chicks from seeing their own toes move by covering their feet with white taffeta cloths resulted in the chicks being nonresponsive to mealworms, their favorite food under usual conditions. The list of examples goes on. What do these findings mean? How have they changed our understanding of instinct?

While there can be no doubt that animals exhibit species-typical and species-specific behavior that is adaptive and is often not dependent on known forms of learning such as associative learning or conditioning, that does not mean that the animals' prior experiences, more broadly considered, are irrelevant. The classic concept of instinct was based on the notion that the epigenesis (development) of behavior, perception, and motivation is *predetermined;* that is, that

genes give rise to structures that function in a unilinear manner (genetic activity → structure → function). However, as experiments on behavior, the nervous system, and genetic activity have shown, epigenesis is *probabilistic* rather than predetermined, in that the relation among genetic activity, structure, and function is bidirectional rather than unidirectional (genetic activity ⇆ structure ⇆ function ⇆ environment). As a result, the present definition of instinctive behavior includes the prior experiences of the individual, broadly construed. Instinct is an outcome of the probabilistic epigenesis of behavior, perception, and motivation, based on the bidirectional coactions among the environment, function, structure, and genetic activity: Instinct is not a special class of behavior in terms of its determinants.

INSTRUMENTAL CONDITIONING

Instrumental conditioning represents a form of behavioral change that depends on the temporal relationship (contingency) between a response and an environmental outcome. The response might correspond to pressing a bar, lifting a leg, turning a wheel, or navigating a maze. In the laboratory, the outcome is typically a biologically relevant event, such as food, water, or a frightening shock. Outside the laboratory, behavior can be modified by a variety of events including social praise, access to a sexual partner, or a stimulus that has acquired value (e.g., money). Outcomes capable of modifying an organism's behavior are sometimes called *reinforcers* and the process through which they influence behavior is known as *reinforcement*. Examples of an instrumental contingency include praising a child for waiting quietly or providing a food pellet to a rat whenever it presses a bar. According to Thorndike's law of effect, these contingencies should bring about a lasting change in behavior, leading the child to stand quietly and increasing the frequency with which the rat presses the bar.

It is clear that the timely application of a reinforcer can bring about a dramatic change in behavior. Anyone who has trained a pet using food as a reward, or attempted to influence a roommate's behavior through social reinforcement, has employed a form of instrumental conditioning. It is important to remember, however, that instituting a response-outcome relationship can sometimes affect performance in the absence of instrumental learning. For example, stimuli that regularly predict an aversive event can be associated with the event through a form of Pavlovian (classical) conditioning. This learning can endow the stimuli with the capacity to produce a conditioned response that affects our target behavior. The problem is that this Pavlovian conditioning can lead us to mistakenly conclude that instrumental (response-outcome) learning has occurred, when in fact the behavioral modification actually reflects the acquisition of a stimulus-outcome relation. Similarly, simple exposure to an outcome alone can cause a response to grow stronger (sensitization) or weaker (habituation) in the absence of an instrumental relation. Demonstrating that instrumental learning is at work requires that we eliminate these alternatives.

Outlining some formal criteria can help us determine whether a behavioral change reflects instrumental conditioning. At a minimum, the following conditions must be met: (1) the behavioral modification depends on a form of neural plasticity; (2) the modification depends on the organism's experiential history; (3) the modification outlasts (extends beyond) the environmental contingencies used to induce it; and (4) imposing a temporal relationship between the response and the outcome alters the response.

The first three criteria specify essential conditions for learning. Because performing the response can alter its vigor through a peripheral modification (e.g., muscular exercise or fatigue), it is important to show that the behavioral change is neurally mediated (criterion 1). Changes attributable to neural development or injury do not count as learning (criterion 2). Finally, because instituting an environmental contingency can bring about a temporary mechanical modification in the response, we must show that our training regimen has a lasting effect on behavior (criterion 3).

The fourth criterion specifies the nature of the behavioral change required for instrumental learning: that the behavioral modification depends on the response-outcome relation. Two operations are used to establish this. One involves the inclusion of a yoked control group that receives the reinforcer independent of its behavior. A second technique degrades the essential relation by imposing a temporal gap between the response and the outcome. If the response-outcome relation is essential, both procedures should undermine the response.

Some instrumental behavior is biologically constrained by the organism's evolutionary history (Timberlake & Lucas, 1989). For example, consider the flexion response elicited by an aversive stimulus applied to the base of the foot. Because this response is organized by neurons within the spinal cord, it can be elicited in the absence of feedback from the brain. This reflex can be modified by imposing a response-outcome contingency; if shock is presented only when the limb is extended, the organism quickly learns to maintain its leg in a flexed (up) position. This modification of a reflexive behavior meets the minimum criteria (1–4) for instrumental conditioning. However, learning within the spinal cord appears biologically constrained. Given the same outcome, we cannot arbitrarily train subjects to exhibit either a flexion or an extension.

More sophisticated neural systems can support a greater range of flexibility. Humans can be trained to lift or lower a hand using a variety of reinforcers (i.e., food, money,

or shock). Such advanced forms of instrumental conditioning meet two additional criteria: (5) The nature of the behavioral change is not constrained (e.g., either an increase or decrease in the response can be established); (6) The nature of the reinforcer is not constrained (a variety of outcomes can be used to produce the behavioral effect).

The term *instrumental conditioning* has its roots in the reflexive tradition of E. L. Thorndike, J. Konorski, and C. L. Hull. From this perspective, instrumental learning reflects a form of elicited behavior, one that depends on the relationship established between a response and an outcome. An alternative view was suggested by B. F. Skinner, who noted that it is often difficult (or impossible) to specify the eliciting stimulus for advanced forms of instrumental behavior. He referred to this type of behavior as *operant conditioning* and argued that it is emitted, not elicited.

These historical facts continue to influence how the terms are used within the modern learning literature. Skinnerians focus on the experimental analysis of behavior and generally employ the term operant conditioning. The emphasis is on emitted behavior and rate of responding. Those that follow in the tradition of Hull assume that response-outcome relations can affect elicited responses and that associative processes underlie complex instrumental behavior.

Because both instrumental and operant conditioning depend on the response-outcome relation, they are sometimes treated as synonyms. However, in cases where the target response is elicited and/or an attempt is made to explain the behavior in terms of associative mechanisms, the term instrumental conditioning is more appropriate.

INTEGRITY GROUPS

Integrity groups (IGs) are a community mental health resource for assisting people in coping with problems of living through self-change. These self-help groups were developed by O. Hobart Mowrer. Integrity groups are based on Mowrer's view that many psychosocial disorders are a consequence of individuals breaking commitments and contracts with significant others in their lives. The indicated remedy for helping someone deal with these concerns is to involve the person in a support group of about eight other similarly engaged individuals.

The social learning approach that characterizes these groups consists of a particular constellation of structure, goals, and shared leadership; group intake in which experienced members model appropriate group behavior; behavioral guidelines and ground rules for conducting weekly meetings; a contractual agreement to practice honesty, responsibility, and involvement inside and outside the group; individual commitments for specific behavior change; an expectation that verbal intentions will be translated into actions; and a considerable amount of group support and reinforcement for behavior change. Group members are available to assist one another as needed during the intervals between the weekly 3-hour meetings. The emphasis on self-responsibility and mutual support is expressed in the IG motto: "You alone can do it, but you can't do it alone."

INTERFERENCE

One of the earliest and most robust findings of experimental psychology is that two event representations in memory can compete with one another. If training on Task A precedes Task B, subsequent testing on Task B may yield impaired (i.e., proactive interference) or facilitated performance relative to control subjects who were not exposed to Task A. Conversely, subsequent testing on Task A may yield impairment (i.e., retroactive interference) or facilitation relative to control subjects who were not exposed to Task B. Such interference is commonly viewed as evidence of competition between the representations of Tasks A and B. Interference (and facilitation) has been observed across a wide variety of subjects (including human and nonhuman species) and tasks. Much of the memory research conducted over the last century has attempted to identify relevant variables (for excellent reviews, old but still relevant, see Postman & Underwood, 1973; Underwood, 1957). The following remarks apply equally to proactive and retroactive interference (and facilitation) except where otherwise noted.

Independent Variables

The most important variables in producing proactive and retroactive interference appear to be (1) the amount of training on each task; (2) the temporal interval between training on the two tasks and between training on each task

and testing; and (3) the similarity of the two tasks, the last of which appears central in determining whether interference or facilitation will be observed. Not surprisingly, more extensive training on a task makes it more apt to impact performance on another task and less apt to be impacted by training on another task. The closer in time the two tasks are to one another, the more apt they are to interact, producing interference (or facilitation) on the test task. Given a fixed interval between Task A and Task B training, the retention interval can be manipulated. Unlike the effects of most other independent variables on interference, which are symmetric between the proactive and retroactive cases, lengthening the retention interval decreases retroactive interference and enhances proactive interference, presumably because a significant portion of retroactive interference depends on a recency effect, and recency effects wane with increasing retention intervals (Postman, Stark, & Fraser, 1968). Task similarity appears to be the prime determinant of whether interference or enhancement will be observed.

One of the most systematic attempts to summarize these relationships was by Osgood (1949). Although his principles were elegantly logical, research has found that only some of them are consistently supported. Let us conceptualize a task as consisting of an eliciting stimulus and an acquired response to that stimulus (e.g., in paired-associate learning, Task A eliciting stimulus = chair, response = banana; Task B eliciting stimulus = stool, response = car). Obviously, two tasks with the same eliciting stimuli and same responses are identical, reducing the Task A–Task B sequence to additional training on a single task; consequently, facilitation is anticipated and, of course, observed. Conversely, when the two eliciting stimuli are highly dissimilar and the two responses are also highly dissimilar, little interaction is expected and little is observed. The interesting cases are when the eliciting stimuli are similar and the responses are dissimilar (or incompatible) as in the above example from paired associate learning, and when the eliciting stimuli are dissimilar and the responses are similar. In the former case, interference is ordinarily observed. But in the latter case, the outcome can range from interference to facilitation, and we do not yet have a simple rule for anticipating which outcome will occur other than experience with prior similar situations.

Theoretical Mechanisms

Several different theoretical accounts have been proposed to explain interference. Available evidence suggests that no single account will suffice (which is not to suggest that all proposed mechanisms contribute equally or even at all in each case). Accounts appear to fall into one of three categories (Miller, Greco, Marlin, & Balaz, 1985; Runquist, 1975): (1) competition for a limited capacity processing system at the time of acquisition (often called "processing interference"); (2) competition between tasks for representation in long-term memory over the Task B test retention interval; and (3) competition for retrieval and response generation at the time of testing (often called "trace interference"). Processing interference appears to take place only when the two competing tasks occur close in time. With this type of interference, task similarity is relatively unimportant. (However, more interference can be expected if the two events use the same sensory modality than in different modalities because the limited processing capacity of organisms appears to be largely segregated by sensory modality.) The second mechanism assumes that the two task (or event) representations compete for a place in long-term memory rather than coexisting with one another. This mechanism would be relevant only when the two events are contrafactual (e.g., acquisition and extinction, or conditioning and counterconditioning). Many researchers deny that this second interference mechanism exists, preferring to attribute all evidence cited in support of this mechanism to trace interference. Trace interference has received the greatest amount of attention, and, not surprisingly, theorizing concerning it is most highly developed. The consistent finding concerning this third mechanism is that the greater the similarity between eliciting stimulus of the interfering task (including nominal, contextual, and temporal cues) and the test conditions, relative to the similarity between the eliciting stimulus of the target task and the test conditions, the greater the interference will be (e.g., Bouton, 1993; Tulving & Thomson, 1973).

Generally speaking, temporal variables (i.e., processing interference) appear to have their greatest impact when the intervals separating Tasks A, B, and testing are relatively short (measured in seconds, e.g., Peterson & Peterson, 1959), whereas the impact of task similarity variables (trace interference) seems to be greatest at longer intervals (Runquist, 1975). This suggests that these variables act through fundamentally different mechanisms (Miller et al., 1985). Seemingly, most interference with short intervals separating Tasks A and B reflects competition between A and B for access to a limited capacity short-term memory. In contrast, interference with longer intervals reflects competition for retrieval and for response generation. These relationships have been well known for over 30 years. Contemporary research on interference (e.g., Matute & Pineno, 1998) has given rise to a plethora of hypothesized mechanisms, but they all appear to fall within the three families of accounts described above.

Permanence

Interference effects in principle can be due either to a potentially reversible lapse in performance (an expression failure) or an irreversible absence of information (i.e., failure to acquire information or loss after acquisition). Each of the three types of mechanisms could, in principle, yield reversible or irreversible interference. But the three types of mechanisms are commonly thought to diverge sharply in

terms of the interference that they produce being reversible or irreversible. The first and second types of interference are generally viewed as resulting in an irreversible absence from memory of the target task representation. In contrast, the third type of interference is usually viewed as yielding a failure to express information that is still retained in memory. Consistent with this view, interference observed with relatively long intervals between training on the two tasks often can be reversed without additional training on the target task. Spontaneous recovery from retroactive interference is one particularly clear case of this. Priming and variation in retrieval cues at test are other often successful means of obtaining recovery from interference; however, these demonstrations are less compelling evidence of a lapse (rather than an absence) of information, because they potentially tap into different representations of the target task than that which was assessed (and found wanting) originally.

An Applied Example

Interference theory is applicable to many practical situations. For example, one contemporary application of interference theory (and controversy in its explanation) is provided by demonstrations that eyewitness accounts of events are subject to retroactive interference, often originating with leading questions from attorneys. One view is that the representation of the original (target) event is irreversibly altered by the (subsequent) interfering event (in our terminology, mechanism type 2; e.g., Loftus, 1975). In contrast, an alternative view is that the representation of the original event is still present in memory but is less readily retrieved because of the interfering event (trace interference; e.g., McCloskey & Zaragoza, 1985).

INTERNATIONAL PSYCHOLOGY

Psychology has been an international enterprise since its beginning as a modern science over a century ago. When most psychologists use the term "international psychology," they are referring to various forms of organized psychology at the international level, including societies, congresses, journals, and other kinds of scientific and professional exchanges. A review by Adair, Coehlo, and Luna (2002) of international databases in psychology revealed a significant presence of organized psychology in 47 countries and a presence of psychology as a scientific discipline in 22 additional countries. Sometimes the term also designates the social psychology of international relations, or the comparative study of psychological processes across different nations and cultures, as in cross-cultural psychology. These last two meanings of international psychology are dealt with only briefly here.

Social Psychology of International Relations

The systematic use of psychological concepts and methods for the development of theory, research, and policy studies in international relations is a relatively new area of specialization within social psychology. Following World War II, various studies of national stereotypes, attitudes toward war and peace, nationalism, and international affairs made significant contributions to an improved understanding of international relations. Generally interdisciplinary in character, these social–psychological approaches deal with the problems of interaction among nations, often with a goal of reducing tension and promoting international cooperation. Among the kinds of research that deal specifically with the international behavior of individuals are studies of national stereotypes or images, attitudes toward inter-

national affairs, national ideology and how it is communicated, and the effects of cross-national contacts upon individual or group behavior. The investigation of intergroup conflict and its resolution has been broadened to include both simulated and naturalistic studies of international negotiation. These and related aspects of psychology applied to international relations are discussed in detail by Herbert Kelman (1965) in his book, *International Behavior: A Social Psychological Analysis.*

International Study of Psychological Processes

Cross-cultural psychology has expanded greatly in the past quarter century. Cross-cultural, comparative approaches are particularly appealing for the study of sociocultural factors in any aspect of human development. The growing realization of parochial limitations in Western psychology, particularly within the United States, has stimulated the development of a new kind of comparative psychology, a comparative psychology of human behavior in markedly different natural settings, rather than a comparative psychology dealing with different animal species. International studies of personality development, cognitive development, and perceptual processes have become commonplace, in spite of the difficult methodological problems encountered in such research.

The most common type of cross-national or cross-cultural study involves only two cultures. Comparisons between two nations are generally very difficult to interpret, because many cultural differences are operating that might provide alternate explanations of the findings, and that cannot be ruled out. The inclusion of subcultural variation and social factors within each nation enhances the likelihood that interpretable results can be obtained. An example of such an international study comparing children studied over a 6-year period in Mexico and the United States is given by Wayne Holtzman, Rogelio Diaz-Guerrero, and Jon Swartz in *Personality Development in Two Cultures.* The intensive study of over 800 children in an overlapping longitudinal design produced clear and uniform differences across the two cultures for many psychological dimensions and test scores, as well as a number of interactions between culture and age, sex, and social class. Six major hypotheses concerning personality differences between Mexicans and Americans were proposed by the authors.

International psychology is only one aspect of cross-cultural psychology, the latter encompassing a much wider range of comparative studies. The search for cultural variation and its consequences for psychological functioning may be limited to a study of cultures within one large multicultural nation, rather than international differences in culture. The first *Handbook of Cross-Cultural Psychology* was published in 1980–1981 in six volumes. Edited by Harry Triandis and William Lambert, the *Handbook* provides a comprehensive review of cross-cultural psychology, the underlying theoretical and systematic approaches, the methodological issues and techniques, and the basic processes that have been studied comparatively, as well as special reviews of developmental psychology, social psychology, and psychopathology as studied from cross-cultural or international perspectives.

Organized Psychology at the International Level

The first International Congress of Psychology was held in 1889, less than 10 years after the founding of the first laboratory of experimental psychology. The rapid exchange of new ideas and methods of research across the different countries of Europe and the Americas produced a truly international psychology with a predominantly Western orientation. Most of the early leading academicians received much of their training in Germany or Great Britain. A long and distinguished series of international congresses served psychology well, but there was clearly a need for an international organization to provide continuity between congresses held only every 3 or 4 years.

At the 13th International Congress of Psychology held in Stockholm in July 1951, the International Union of Psychological Science (IUPsyS) was formally established. The IUPsyS is the only international organization that has as its members national psychological societies rather than individuals. The 11 psychological societies that served as the charter members in 1951 were from Belgium, France, Germany, Great Britain, Italy, Japan, the Netherlands, Norway, Sweden, Switzerland, and the United States. By 2002 the Union had grown to 68 national societies and 12 affiliated international organizations, representing most of the psychologists in every country with an appreciable presence of psychology as both a scientific discipline and an applied profession. *History of the International Union of Psychological Science* (*IUPsyS*) provides a detailed account of the international nature of organized psychology from its inception in 1889 to 2000 (Rosenzweig, Holtzman, Sabourin, & Belanger, 2000).

Organizing an international congress every 4 years is the most important activity of the Union. The 27th International Congress of Psychology, held in Stockholm, Sweden, attracted nearly 6,000 psychologists and guests who participated in over 680 symposia, workshops, and related scientific sessions. The 28th Congress will be held in Beijing, China on August 8–13, 2004.

The major aims and objectives of the Union are to promote the exchange of ideas and scientific information among psychologists of different countries, to foster international exchange of scholars and students, to collaborate with other international and national organizations in promoting psychology as a science and profession, and to encourage international projects that will further the development of psychology. An example of such projects is the organization of advanced research training seminars for

young psychologists held in proximity to the world congresses.

One of the most important projects of the Union in the past was the compilation and publication of the *International Directory of Psychologists.* The fourth edition of the *Directory,* edited by Kurt Pawlik, lists over 32,000 psychologists from 48 different countries, excluding the United States, where the American Psychological Association and the American Psychological Society already publish readily available directories of their members. In the past 15 years the number of psychologists throughout the world has increased so rapidly that a single directory of individuals is no longer possible, even excluding the several hundred thousand psychologists in the United States. Together with Psychology Press, Ltd., the Union electronically publishes specialized international directories of research institutions and resources on compact computer disks, the first of which is *Psychology: IUPsyS Global Resource* (Overmeier & Overmeier, 2002).

In 1975, the three-volume *Trilingual Psychological Dictionary,* edited by Hubert C. J. Duijker and Maria J. van Rijswijk, provided a standard technical vocabulary for translating psychological terms from English, French, or German into either of the other two languages. Since then, the publication of similar bilingual dictionaries for translation between English and another language have greatly expedited standardized translation of psychological works. An example is the *Concise Encyclopedia of Psychology,* edited by Q. C. Jing, which defines in Chinese the many technical terms in psychological science.

Another kind of publication promoting international psychology provides English summaries of articles and books published originally in a different language. The *German Journal of Psychology, French-Language Psychology,* and *Spanish-Language Psychology* have set the standard for the exchange of scientific information across languages. Since nearly 90% of the articles and books in psychology are published originally in English, and since most psychologists can read English, *Psychological Abstracts* and its electronic version, *Psyc-SCAN,* provide readily available, English-language abstracts of articles in the leading psychological journals throughout the world.

Most international organizations in psychology have individuals rather than societies as members. The oldest is the International Association of Applied Psychology, founded in 1920 by Edouard Claparede. As in the case of IUPsyS, the International Association of Applied Psychology sponsors a world congress every 4 years. At the 24th International Congress of Applied Psychology, held in San Francisco in August 1998, applied psychologists from throughout the world participated in symposia, workshops, general sessions, and individual paper presentations devoted to such fields as industrial, clinical, counseling, and school psychology, applied social or experimental psychology, and educational psychology, usually from an international or cross-cultural perspective. Between congresses, the Association sponsors international projects and exchanges such as the International Test Commission. A number of special interest divisions within the Association deal with more narrowly defined international issues in applied psychology.

Smaller international organizations also exist to meet the specialized international interests of psychologists. Illustrative of such organizations are the International Council of Psychologists, the International Association for Cross-Cultural Psychology, the Interamerican Society of Psychology, the European Association of Experimental Social Psychologists, the European Association of Personality Psychology, the European Association of Work and Organizational Psychology, the European Federation of Professional Psychologists, the International Association of French-speaking Psychologists, the International Neuropsychology Society, the International Society of Comparative Psychology, and the International School Psychology Association.

The above associations are comprised almost entirely of psychologists. Some interdisciplinary associations also have large numbers of psychologists as members. Leading examples of such associations are the International Brain Research Organization and the International Society for the Study of Behavioral Development.

The development and status of psychology in different countries and regions of the world vary considerably. As one would expect, the most highly developed scientific psychology exists in North America, Europe, and Japan. Rapid growth in the post-World War II period has also occurred in Australia, Brazil, and Mexico, with several other countries of Latin America and Asia close behind. Surveys of trends in the development and status of psychology throughout the world, as reviewed by Mark Rosenzweig (1992), editor of *International Psychological Science,* suggest that there are well over a half million recognized psychologists throughout the world. The most rapid growth has occurred among practitioners rather than research scientists. The greatest concentration exists in the United States and Canada, followed closely by Western Europe. If one could count all the individuals engaged in some kind of psychological research or practice, the actual number would be far greater. International comparisons are complicated by the fact that some countries may require a doctoral degree for full membership in their national psychological societies and for most professional positions, while other countries may require only a professional certificate after 5 years of university work.

Psychology is a discipline cultivated mainly in the industrialized countries, although the developing countries are rapidly catching up. While the scientific principles of psychology are valid regardless of cultural boundaries and politics, the scientific status of psychology and its social relevance vary greatly throughout the world.

INTERPERSONAL COMMUNICATION

Attempts at defining interpersonal communication date back to the Golden Age of Greece. Plato and Aristotle discussed communication in terms of rhetoric. However, several millennia later there is still no generally agreed upon scientific definition of communication. According to Webster's *New World Dictionary* (1966), "to communicate" is defined as "to impart, pass along, transmit," and "communication" is defined as "giving and receiving of information, signals or messages by talk, gestures, writing, etc." These definitions are helpful as orientations to this area of study, but lack sufficient detail or specificity for scientific purposes.

The notion of transmission of information has been applied to genetic materials as well as nonorganismic events. An individual might transfer information from one cognitive context to another in a form of intraindividual communication. Furthermore, categories representing intergroup, interorganizational, international, and (in science fiction) intergalactic communication could be developed. Interpersonal communication refers to the transfer of information by a source to a specific target. These communications typically occur in face-to-face interactions, although they may also occur by mail, telephone, television, the Internet, or other electronic means. Lasswell (1948) captured in one sentence much of the subject matter of human communication: "Who says what in what channel to whom with what effect?"

Electrical engineering principles were applied by Shannon and Weaver in 1949 to human communication. Figure 1 shows their model of the communication process. The mind of the communicator may be considered the source of the communication. Presumably, messages originate in the brain and are encoded for transmission to other people. The source must have a means of transmitting information, such as speech, gestures, or writing. The message is encoded and sent as a signal to a receiver, who must decode the message. Thus, the destination of a message is the mind of a target or receiver person.

This information model is helpful in examining some of the more important questions regarding interpersonal communication. It should be noted that the source may unintentionally communicate to others, as when nonverbal cues betray a liar. Of course, the source may not even be aware of a communication. For example, a person may communicate liking for another by maintaining a rather close physical proximity, but may be unaware of doing so.

Intentional communication may be examined in terms of the degree to which the interpretations of the source are accurately received by the target. For some communication theorists it is the sharing of interpretations and not just the exchange of information that lies at the heart of the communication process. Any interference with accurate transfer of information is referred to as *noise* in the system. Noise may be due to ambiguous encoding, problems with channels through which signals are transmitted, or faulty decoding by the target. If, for example, the source transmitted a message in German and the target understood only English, noise would be attributable to the target's inability to decode the communication. If two persons were talking over the telephone but could not hear each other because of static over the lines, noise would be located in the channels being used. One should not construe disagreement between two persons as necessarily caused by noise. A target may be able to take the viewpoint of the source and fully understand the interpretation communicated, but nevertheless disagree with it. Often persons believe they have not been understood, when in reality the target persons disagree with them.

There has often been confusion even among scientists in distinguishing between language and communication. To make the distinction, one must understand the differences between signs, signals, and symbols. Signs are environmental stimuli which the organism has associated with

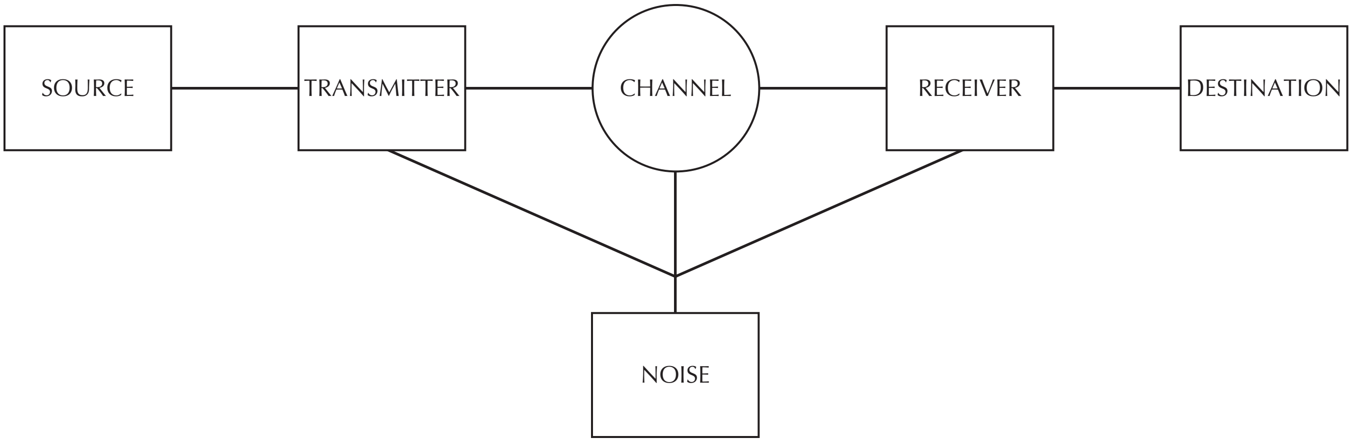

Figure 1. A schematic of a communications system (after Shannon & Weaver, 1949).

other events. For example, a hunter may associate certain prints in the dirt as a sign that a deer has recently passed nearby. Signs are inflexibly and directly related to their associated events.

Signals are signs produced by living organisms. Most animals can use signals in their interaction with other animals. Thus, birds may emit love calls, insects may transmit odors, and monkeys may manifest threat gestures. Research by Gardner and Gardner (1969) has shown that chimpanzees can be taught to use complex signals often taught to deaf and/or mute humans. However, even the most intense training results in fewer than 400 signals learned by these higher primates. Nevertheless, the ability of these animals to communicate is clearly greater than previously thought possible.

A symbol, like a signal, has a referent. However, symbols do not necessarily refer to physical reality and may not have space–time relationships as their referents. Symbols derive their meaning from a community of users and not from a connection with a referent. The use of symbols allows the development of various abstract areas of knowledge such as history, literature, religion, art, and science. Furthermore, it provides the basis for the individual's construction of social reality, including a self. The available evidence (Gardner & Gardner, 1969) indicates that only humans use symbols. Chimpanzees appear to be confined to the existential moment and cannot escape their time–space coordinates. Although they can remember and signal what they did an hour ago, they cannot report what they did yesterday or reveal plans about the future. Thus, it appears that the symbol represents an important discontinuity in phylogenetic development between humans and all other forms of life.

Language is a means of information processing and is used to store, manipulate, create, and transmit information. No analysis of interpersonal communication among humans would be complete without a consideration of the symbolic aspects of language. Two important properties of symbols are that they may refer to classes of things, and they may have multiple meanings. Thus, errors in communication are both frequent and inevitable; that is, noise tends to be an inevitable feature of interpersonal communication.

Situations and relationships with others provide contexts within which persons can share interpretations of communication and hence reduce noise. The individual's definition of the social situation typically involves certain expectations about the behavior of others, the rules that define and regulate interactions, and guides to conduct. These expectations provide a frame of reference within which the person encodes and decodes information. For example, "Did you buy the pot?" means something different when communicated on a street corner between teenagers than when transmitted from a mother to a daughter.

Communication has a number of functions. It allows the coordination of behaviors of individuals in a group. Large corporations and government bureaucracies require a great deal of communication among employees at all levels in order to function at all. Interpersonal communication also allows for instruction, in which one individual helps another to learn skills or develop new frames of reference. Perhaps most important of all, communication functions as a means to influence others. Messages used for purposes of power and influence may be considered actions with as much impact as skeletal behaviors. Thus, communicative actions are sometimes referred to as speech acts.

Speech acts that refer to rewards and punishments take the form of threats or promises which may be contingent or noncontingent in form. A contingent threat specifies that a target must comply with some demand of the source or else suffer some cost to be inflicted by the threatener. A noncontingent threat announces the source's intention to impose some cost on the target without any demand for compliance being made. A contingent promise offers a reward, if the target complies with a request by the source. A noncontingent promise simply announces the source's intention to reward the target. Promises, unlike threats, carry a moral obligation of fulfillment by the source.

There are several speech acts that may be classified as means of information control. Persuasion represents a source's attempt to influence a target's decisions. Among the types of persuasive communication are warnings, mendations, and activation of commitments. Warnings convey expectations of future negative events not controlled by the source, while mendations are predictions of positive events not controlled by the source. Activation of commitments consists of exhortations appealing to the normative values of the target in order to induce some related behavior by the target.

Another classification of speech acts refers to their function as self-presentational. Actors project certain identities to others and engage in various tactics to foster desired identities in the eyes of others. Among the more prominent speech acts devoted to impression management are accounts, entitlements, and enhancements. When a person does something that seems strange, untoward, or abnormal to others, an explanation is usually offered or demanded. The lack of an explanation leaves an unfavorable impression and may lead observers to blame and perhaps punish the actor. Accounts are explanations for untoward behavior and consist of excuses and justifications. Excuses are explanations that deny responsibility for negative effects of behavior. Excuses may deny intention to produce the effects, or may deny that the source had volitional control over the actions in question. Denials of intention refer to lack of foreknowledge, mistake, inadvertence, and accident. Denials of volition may refer to drugs, alcohol, physical disability, or mental illness (insanity). Justifications are explanations of actions that admit responsibility but offer legitimate reasons for them. For example, a person may justify spanking children as a way to teach them not to run out into the street. Justifications may appeal to authority, ideology, norms of justice, self-defense, or self-actualization.

Entitlements are speech acts in which the source attempts to take responsibility for positive events. Enhancements are attempts to embellish the value of the positive consequences. People want credit for positive consequences because they gain approbation and rewards for such actions. The more positive the consequences, the greater the credit; hence, actors are motivated to use enhancement tactics.

Gestures, visual contact, body orientation, and the use of interpersonal space may substitute for verbal communication or may serve as a context within which to interpret verbal communication. In many instances, nonverbal responses act as signals and do not convey symbolic forms of information. For example, eye contact may communicate hostility or love, or indicate that the source is acting deceitfully.

INTERPERSONAL PERCEPTION

The impressions we form of other people serve as important bases for interpersonal interactions. Person perception is a complex topic and clearly different from space perception. The latter is concerned with how perceptions of physical reality are mediated and tends to focus on biochemistry, biophysics, and/or psychophysics; the researcher attempts to relate cognitive factors to physical ones through the pathways provided by the sensory apparatus of the organism. In person perception the observer is concerned with the interior psychological processes of stimulus persons: what are they feeling, what plans do they have for future action, what effects do they intend to produce in the environment, and what causes them to act the way they do? These questions have little to do with sensory mechanisms, but instead are answered by inferences or attributions made by the observer. In a way, person perception is a misnomer which perhaps would be better expressed as "person inferences." Much of the topic is currently referred to as attribution theory, or more generally as social cognition.

In his seminal work, *The Psychology of Interpersonal Relations,* Fritz Heider (1958) noted that there are three differences between the perceptions of objects and persons. First, persons are assumed to experience an interior life and objects are not. Each person experiences thoughts and emotions, and assumes that others do also. Second, objects are not perceived as causes of their own actions, whereas persons are often viewed as first causes. The concept of responsibility is inextricably interwoven with the notion that one acts for one's own interior reasons, rather than in response to the inexorable forces of the environment. Third, persons can deliberately manipulate and exploit the perceiver, while inanimate objects cannot. One purpose of person perception is to allow the observer to predict the probable actions of the stimulus person, so as to anticipate in planning his or her own actions.

The study of person perception is essentially an attempt

to reconstruct the way the average person processes information about other people and the self. The observer is interested in answering the question of why the stimulus person acted as he or she did. Thus, the average person acts as a naive psychologist in seeking explanations for behavior. According to Heider (1958), causes for behavior are attributed to either the environment or the person. Environmental forces may be perceived to be so strong as to move actors around as if they were pawns on a chessboard. On the other hand, the person may be seen as the origin of action, even acting against strong environmental currents. When the action can be attributed to environmental causes, the actor is not held responsible for the positive or negative effects of his or her behavior, but when factors inside the actor are perceived as the origins, the actor is held accountable for the effects.

Much of the work done in the area of attributions is concerned with the rules that observers use in attributing cause to the environment or the person. For example, suppose an automobile swerves toward a sidewalk and runs over and kills a pedestrian. Is the death (an effect) attributable to environmental factors, such as a mechanical failure, or a reaction to another car that sideswiped the automobile and so caused the death? Or is the death attributable to deliberate intention to commit murder, or perhaps to the inebriated condition of the driver? Which of many potential causes actually produced the effect will determine how others react to the driver.

The tendency of observers is to accept the first sufficient cause as the reason for behavior. The impact of any particular cause in producing an effect is discounted, however, if other plausible causes are present. This discounting principle may lead to attributions to both environmental and person causes of behavior. Furthermore, the more effects the observer believes are associated with the actor's behavior, the more plausible causes there can be. Harold H. Kelley (1973), who proposed the discounting principle, also suggested an augmentation principle: the more costs the actor risks in order to act as he or she does, the more likely the observer is to attribute the behavior to person causes. Thus, the more embarrassment, pain, criticism, penalty, or punishment the actor suffers, the more likely an observer will attribute the behavior to something about the person. On the other hand, when the actor does what most other people would do in the same situation, observers would not believe they had learned anything much about this particular actor. The rule of thumb is that the more the actor's behavior deviates from what the observer believes most people would do, the more likely the action is associated with something peculiar about this actor. Of course, different observers may have different expectations about the so-called average or typical person, and hence may apply the augmentation principle somewhat differently.

An observer may observe an actor only once or may have multiple opportunities to witness behavior. Most attributional rules can be categorized as based on either a single observation or on multiple observations. Among the former are the following:

1. *Out-of-role behavior.* People are often rewarded for playing certain roles and meeting the expectations of others. For this reason, people tend to conform to role demands and expectations. When a person violates the norms governing a role, the out-of-role behavior is attributed to the person, who is apparently acting against environmental constraints. Out-of-role behavior can be construed as derivative from the augmentation principle. The person who is out of role has given up customary rewards and is apparently willing to accept negative reactions from others. The action must stem, therefore, from some inner personal factors.
2. *Noncommon effects.* An observer may mentally reconstruct the decision making of the actor in order to understand the choices made. Each choice alternative would presumably bring about desired effects for the decision maker. It may be assumed that the chosen alternative is preferred because it maximizes some value for the actor, at least as compared to the other alternatives. That is, some effect that is noncommon to the decision alternatives is the basis for the decision that is made, and that effect reveals something about the decision maker.
3. *Hedonic relevance.* When the actions of another person have some positive or negative impact on the observer, the latter has a stronger tendency to attribute the behavior to personal causes. That is, the observer is more apt to make environmental attributions when the actor's behavior affects other people than when it affects the observer.
4. *Personalism.* When the observer experiences positive or negative effects from the actor's behavior, consideration will be given to whether those effects were specifically aimed at the observer. When the observer believes the behavior was directed at him or her (personally), the observer more confidently makes a person attribution.

Kelley (1973) has provided a model of the rules used by naive observers in making attributions after multiple observations of an actor. If the observer does not have a ready causal schema within which particular actions are analyzed, causes attributed, and responsibility assigned, he or she will rationally process the data available, much as a scientist would. Suppose, for example, that someone tells you they liked a particular movie. Is this reaction to the movie due to something about the person, or is it because the movie is really good (i.e., an environmental cause)? To answer this question, the observer can assemble all the infor-

mation he or she has about the movie reviewer. According to Kelley (1973), the following principles will allow the observer to make attributions to the person and/or the environment:

1. *Consistency.* If the reviewer saw the movie more than once and liked it both times, it would seem unlikely that some personal factor such as a temporary mood or state of emotion, which would tend to fluctuate and change over time, could account for the reaction to the movie on both occasions. The movie is part of the physical environment, which is experienced as stable and relatively unchanging, and would seem a more likely cause of the reaction. Thus, consistency of reaction suggests a stable environmental cause, while inconsistent reactions suggest fluctuating personal causes.
2. *Distinctiveness.* If a reviewer likes all movies seen, one would tend to attribute the reaction to personal causes. After all, some movies are excellent, some are good, and then there are the others. A reviewer who does not have distinctive reactions to movies apparently does not react to the differences between them, hence appears to react more on the basis of internal personal factors. Generally speaking, then, the more distinctive the person's response, the more apt an observer is to make an environmental attribution, and the less distinctive the response, the more likely a personal attribution will be made.
3. *Consensus.* If a large number of people react in the same way to a situation, an environmental attribution will be made. However, if a person reacts in a manner different from most other people, a personal attribution is more likely. In the case of the movie reviewer, if a large number of people agree with the reviewer's reaction, it will be attributed to the film and not to anything about the reviewer. However, if the reviewer's reaction is idiosyncratic, the reaction will be attributed to something about the reviewer rather than to the film.

There is a tendency for divergences in attributions between actors and observers. Actors usually cannot do everything they most desire, but must act within the context of obtaining the best outcomes possible under the circumstances. As a result, actors tend to see their own actions as strongly constrained by the environment. On the other hand, as Heider (1958) has noted, the behavior of the actor tends to engulf the perceptual field of the observer. This focus on the actor to the exclusion of the environment is referred to as the fundamental attribution error and leads observers to make stronger personal attributions than do actors. Also, of course, actors have more information about themselves and a wider context of attribution than do observers.

Jones and Davis (1965) have argued that once an observer makes an attribution to personal causes, a corresponding inference will be made from the characterization of the behavior that was observed and the motive that is inferred as underlying that behavior. The observer notes effects that occur in the environment and traces these back to the behavior of an actor. If the behavior is attributed to environmental factors, the information processing ceases. However, if a personal attribution is made, the observer assumes the actor intended the effects observed. Intent implies that the actor has foreknowledge of the effects and the ability to produce them. Intent refers to the effects and not to the behavior in question. If intent is attributed to the actor, a motive for the intention is inferred. The difference between intent and motive is that the former is an "in order to" reason and the latter a "because of" reason. That is, a forward-oriented reason that the behavior was emitted to produce the effects is an intention, whereas a motive is backward looking and gives a reason for wanting to produce those effects.

Correspondent inference assumes a commonality between the nature of a response and the motive attributed for it. For example, domineering people may have a power motive attributed to them. This theory, offered by Jones and Davis (1965), assumes that whenever an observer makes an attribution of cause to the person, a correspondent inference will be made. It must be further assumed that the identification and labeling of responses is unproblematic and is a given, much like the proximal energies of space perception. It can be argued, however, that an action cannot be identified apart from the goals assumed to guide the actor. For example, a man pulling and pushing a pump handle could be described as exercising his back and arm muscles or as pumping water into a trough. Which description is more "accurate" would depend on what the man's goals were believed to be.

Clearly, observers do form overall impressions of other people. Information is gathered from direct observations and from reports by other observers. The first impression of an actor tends to have a stronger impact than later information. This primacy effect may occur because earlier information serves as a context within which later information is interpreted. Some kinds of information are more central in forming overall impressions, and other information is more peripheral or unimportant. For example, describing someone as warm or cold has been shown to have more impact on overall impressions than describing the stimulus person as polite or blunt. Anderson (1965) has proposed mathematical models of how observers process and weigh information provided (in adjectival form) about actors. How likable a person is may be more heavily weighted by some traits than others, and earlier information may be given more weight than later information. The primacy effect may be due to the discounting of later information or may occur by inattention after an early impression is formed. These ideas can be presented in the form of an al-

gebraic weighted averaging model, which has received rather impressive support from empirical studies.

Social psychologists have had a traditional concern about the accuracy with which observers attribute emotional states and personality traits to actors. Observers have been presented idealized paintings, photographs, motion pictures, and live actors portraying various emotions, and have been asked to identify the emotion expressed. If one accepts the labels given to stimuli by scientists as the criterion, then observers are fairly accurate in identifying emotions from viewing only facial expression, hand movements, still photographs, and voice inflections. Furthermore, there is rather good agreement across very different cultures in making these attributions to identical stimuli. The latter finding has provided some support for the Darwinian belief that human expressions have evolved through the phyla. Viewing cues in social context allows observers in all cultures to provide more "accurate" labels of emotional states. But there is a criterion problem with much of this research: There is no satisfactory definition of what exactly an emotion is, hence it is not very clear how one identifies any particular state.

Observers tend to assume that other people will behave consistently over time. To attain a view of the world as orderly and predictable, the observer tries to maintain organized and meaningful impressions of other people. It might even be said that observers will invent some constancy to characterize others, such as underlying stable dispositions, so as to make sense out of the diversity of behavior. Each person tends to develop an implicit theory of personality in which certain kinds of traits and dispositions are viewed as being mutually associated or dissociated. For example, an observer who makes a correspondent inference that another person has a power motive may then construct, through a chain of inferences, a belief that the stimulus person has a series of other traits (strong, exploitative, aggressive, cold, impolite, etc.). While there may be some commonality of implicit personality theories within a given culture, there is considerable variation as well.

Observers will often cluster traits together as descriptive of a particular category of people. This picture in our heads is referred to as a stereotype. A social stereotype exists when a sizable group of people agree on the category-based cluster. A stereotype of Italians, for example, may include that they are musical and passionate. Presumably, if the only information an observer has regarding a given actor is that the individual is Italian, any future interaction between them may be based on the belief that the actor possesses the stereotypical traits. In this sense stereotypes help to organize perceptions and to provide a basis for predicting what strangers are likely to do. While there may be a grain of truth in some stereotypes, at least as they apply to entire groups of people, they tend to present an impoverished and inadequate basis for understanding and interacting with individuals.

An important stereotype recently investigated by social psychologists refers to beautiful women. It is generally believed that beautiful women have more dating opportunities and more socially desirable personalities, and are happier and more intelligent. Beautiful women may also have an advantage in job interviews and performance ratings. However, there is evidence that at higher levels of management, physical attractiveness is an asset for men but a handicap for women.

Most of the literature on interpersonal perception assumes that a stimulus person is inert and merely stands (as for a portrait), while the observer draws inferences from the behavior performed. However, the actor may have much to gain or lose from the impressions given off by behavior, and hence is motivated to affect them in some way. Thus, the actor may engage in one or more of a numerous assortment of possible impression management strategies to negotiate an identity in the eyes of the observer.

Impression management may be defensive in remedying a spoiled identity resulting from negative behaviors, or in warding off negative impressions in advance of behavior. For example, the actor may offer accounts or explanations for a problematic behavior. Such accounts may take the form of excuses, generally helping the observer to make environmental attributions for the behavior, or justifications that argue that the beneficial effects of the behavior outweigh the negative effects. Impression management behaviors may also be assertive in the sense that the actor tries to establish a preplanned identity in the eyes of the observer. For example, when positive effects are produced by behavior, the actor will try to get the observer to make a personal attribution. If a personal attribution is made, the actor will gain responsibility and credit for the positive effects, and is apt to gain approbation or other rewards for so doing.

Rules of decorum and demeanor often require that an observer accept an identity presented by another. To challenge that identity may be taken as an insult and generally would not lead to smooth interactions between the two parties. On the other hand, an observer cannot allow an actor to establish any identity whatsoever, since to do so would give control of the interaction to the actor. Thus, there is a tendency for people to negotiate their identities in front of one another.

The study of interpersonal perception has not yet incorporated the dynamic interaction proposed by impression management theory. The attribution process appears to be static and perhaps relies too much on rational models of information processing. Future focus is likely to examine strategies of impression management and how observers penetrate attempts to control their impressions in forming judgments of actors.

INTERPERSONAL PSYCHOTHERAPY

For at least a century, since Sigmund Freud invented psychoanalysis, psychotherapy has been an important part of psychiatric treatment. Yet until recently, the utility of talking treatments rested on therapists' belief rather than research data. Hundreds of psychotherapies arose, many developed by charismatic therapists, but none had an empirical basis. Only in the last 30 years have psychotherapies been carefully tested to see when they are helpful and when they are not. Interpersonal psychotherapy (IPT) is one of still few psychotherapies to have undergone rigorous testing and been shown to help patients with specific psychiatric diagnoses.

IPT was developed in the early 1970s by the late Gerald L. Klerman, MD; Myrna M. Weissman, PhD; and their colleagues at Harvard and Yale. In planning a medication treatment study for outpatients with Major Depressive Disorder (serious clinical depression), and recognizing that many patients in clinical practice received talking therapy as well as pills, Klerman and Weissman decided to add a psychotherapy to their study. Being researchers, they developed a manual-based treatment that relied on known psychosocial aspects of depression. They knew that serious life events can trigger depressive episodes in individuals who are vulnerable to developing depression, and that, once depressed, many individuals have difficulties in interpersonal functioning that result in further demoralizing life events. In other words, life events affect mood, and mood affects life circumstances, in a potentially vicious cycle. Further, research had shown that social supports provide protection against developing depression, whereas conflicted relationships increase depressive risk.

Based on such findings, and on interpersonal theories by psychiatrists from the 1950s such as Harry Stack Sullivan and the attachment theory of John Bowlby, Klerman and Weissman constructed a psychotherapy manual and trained psychotherapists to use it. What emerged as IPT is a life events-based, diagnostically targeted, straightforward, pragmatic, optimistic, forward-looking rather than past-focused, and empirically rather than theoretically driven treatment. Principles of IPT include

1. A formal time limit, to allow comparison to medications in research trials, and to accelerate treatment results.
2. A supportive, encouraging relationship with the patient.
3. Two definitions of the patient's situation. First, the patient is given the diagnosis of major depression, which is presented as a treatable medical illness rather than a character flaw (which is how the patient often perceives it). Patients are given the "sick role," a temporary status that recognizes they are suffering from an illness and probably cannot function at full capacity. Depressed patients learn to blame the illness when appropriate, rather than guiltily blaming themselves as they are wont to do. The sick role also incorporates the responsibility to work in treatment toward recovery, at which point the patient reassumes a healthy role.
4. The time-limited treatment is then focused on one of four areas: *complicated bereavement* (an aberrant response to the death of a significant other), *role dispute* (a struggle with a significant other), *role transition* (a major life change, such as in job, geography, marital status, or health), or *interpersonal deficits* (a poorly named category that really denotes absence of any of the first three kinds of life events).

In each weekly, 50-minute session, therapist and patient review what has happened between sessions and connections between the patient's recent mood and recent life situations. Sessions focus on the patient's interpersonal skills; for example, depressed patients typically struggle to assert themselves, confront other people, and take social risks. When patients handle interpersonal situations appropriately, therapists reinforce their use of social skills and underscore the link between good social functioning and improved mood. When interpersonal events go badly, therapists help patients to understand what went wrong and to prepare to handle future encounters more adaptively.

Randomized controlled trials of IPT showed that it relieved depression better than control conditions and with roughly equivalent efficacy to antidepressant medications. Moreover, IPT helped patients to build social skills, which medication alone did not. The success of IPT in studies of outpatients with Major Depressive Disorder led to its testing for patients with other mood and nonmood diagnoses, including major depression in medically ill patients, depressed geriatric and adolescent patients, mothers with postpartum depression, Dysthymic Disorder, and as an adjunctive treatment for bipolar disorder; it has also been

tested for bulimia, social phobia, Post-Traumatic Stress Disorder, and other conditions. For many of these syndromes, researchers developed new manuals to adapt IPT to the particular psychosocial needs of patients with the target diagnoses. Only in two studies of patients with substance abuse has IPT not been shown to be helpful.

Used mainly as an acute (12 to 16 week) individual treatment, IPT increasingly has been tested in other formats: as couple's therapy, group therapy, telephone therapy, and as a 3-year maintenance treatment for patients with recurrent depression who improved after acute treatment. Indeed, IPT is the only psychotherapy fully tested as a maintenance treatment for patients with recurrent episodes of major depression. Even in a low, once monthly dosage, it protected against relapse better than pill placebo, although not as effectively as high dose maintenance antidepressant medication. In some acute studies and one of the two maintenance studies, the combination of IPT and medication worked better than either treatment alone.

Research on IPT has focused largely on outcome, that is, symptomatic improvement. Its success in this area has led to the inclusion of IPT in American and international treatment guidelines for depression and bulimia. Other research domains also deserve exploration: which of the eclectic ingredients of IPT help which patients; when IPT might be preferable to, or less helpful than, other treatments such as cognitive-behavioral therapy; and how well IPT works in general practice. Some research has begun to reveal biological and psychological outcome predictors as well as neuroimaging brain changes due to IPT. Initially a purely research therapy, IPT is now beginning to expand beyond its research origins into clinical practice, spawning an International Society for Interpersonal Psychotherapy and addressing questions of appropriate standards for certification of IPT proficiency by nonresearch therapists.

INTERVENING VARIABLE

An intervening variable is an unobservable link between two observed variables. Many of our assumptions about the causes of human behavior postulate an intervening psychological variable that mediates between the stimulus and response. For example, imagine two children on the playground. George bumps Sam, then Sam hits George. The stimulus (being bumped) presumably caused Sam's response (hitting George). However, in order to understand the causal link, we need to postulate an intervening variable. Sam is bumped (the stimulus); Sam thinks, "George hurt me, so it's fair to hurt him back" (the intervening variable); then Sam hits George (the response). The introduction of an intervening variable allows us to understand why people react differently to the same stimulus. For example, William runs away when George bumps him, but David laughs when George bumps him. Perhaps the intervening variable for William is his thought, "George is stronger than I am. If I don't run, he'll hit me again." When George bumps David, David laughs, perhaps because he interprets the bump as another example of George's playfulness or clumsiness.

The intervening variable is not observable. We observe two things: the stimulus (getting bumped by George) and the response (hitting George, running away, or laughing). Psychotherapists work with clients to understand the intervening variables that lead to maladaptive responses. Psychoanalysts may look for intervening variables related to early life experiences. Cognitive therapists may help people replace unacceptable intervening variables (e.g., negative self-talk) with more adaptive ones (e.g., positive self-talk). For example, a client who is afraid of the dark may be taught to redefine darkness as relaxing and nonthreatening. Albert Ellis's rational-emotive psychotherapy is based on the concept that cognitive intervening variables can be changed.

Psychologists explain consistencies in human behavior by postulating intervening variables that are relatively stable characteristics of individuals, such as personality traits or abilities. It might be postulated that Sam is pugnacious, William has low self-esteem, and David has a good sense of humor. This interpretation can be tested by observing the children in a variety of situations.

The interpretation of a response depends on what intervening variable is applied. Imagine that a child just failed an exam. It can be postulated that the intervening variable is competence, the motivation to study hard, or the support of caring parents. Did the student fail because of ability, motivation, or parental assistance? How the intervening variable is interpreted affects the decision about how to help the child improve. Should the child be moved to a lower-level class or be provided with better motivation, or should a therapist or teacher work with the parents? If the wrong intervening variable is selected, the remediation may be ineffective. Psychologists use interviews and tests to assess intervening variables.

Psychological theories postulate intervening variables such as ego strength, locus of control, and cognitive dissonance. These unobservable variables provide theoretical links between stimuli and responses. An effective intervening variable allows psychologists to better understand and predict behavior.

INTRINSIC MOTIVATION

Intrinsic motivation is a type of motivation based in people's inherent interest in activities that provide novelty and challenge. Intrinsically motivated behaviors are an expression of an individual's self and do not depend on external reinforcements. Thus, intrinsically motivated behaviors have what is referred to in attribution theory as an internal perceived locus of causality; people experience the causes of these behaviors to be within themselves (deCharms, 1968).

Throughout life, when in their healthiest states, people are active and curious, displaying an eagerness to learn and explore. This natural, intrinsic motivation helps people acquire knowledge about themselves and their world.

Until the 1950s, theories of motivation focused on physiological drives such as hunger, thirst, and sex, proposing that all behaviors are motivated by those drives and their derivatives (Freud, 1962/1923; Hull, 1943). However, as various phenomena emerged that could not be explained by drive theories, White (1959) suggested that a full understanding of motivation required a consideration of psychological needs as a motivational basis for some behaviors. He proposed an intrinsic motivation for interacting effectively with the environment; Deci and Ryan (1985) subsequently stated that the psychological needs for competence and autonomy underlie intrinsic motivation, which flourishes in contexts that allow satisfaction of those needs.

Whereas drive theories implied that humans seek quiescence and minimal stimulation, intrinsic motivation theories suggest that people desire an optimal level of stimulation. The structure of intrinsically motivated behaviors thus involves an ongoing cycle of finding stimulation and working toward quiescence. In other words, people seek and conquer optimal challenges.

Behaviors such as reading a book, solving puzzles, exploring novel spaces, looking at paintings, and playing softball are intrinsically motivating for many people, but not necessarily for all, because intrinsic motivation is a property of the interaction between a person and an activity. For an individual to be intrinsically motivated for an activity, that individual must find the activity interesting.

Intrinsic motivation is typically contrasted with extrinsic motivation. People are extrinsically motivated for an activity when they do it to earn money, avoid censure, or comply with social norms.

Numerous studies have confirmed that, relative to extrinsic motivation, intrinsic motivation leads to better conceptual learning, greater creativity, more cognitive flexibility, and enhanced well-being (see Deci & Ryan, 1985). Consequently, there has been great interest in the conditions that enhance versus diminish intrinsic motivation. Initial studies examined how extrinsic rewards affect intrinsic motivation, and a recent meta-analysis substantiated that tangible extrinsic rewards undermine intrinsic motivation for rewarded activities (Deci, Koestner, & Ryan, 1999).

Additional studies with young children, teenagers, college students, and adults revealed that other external events, such as directives, surveillance, deadlines, threats of punishment, and negative performance feedback also decrease intrinsic motivation. By contrast, events such as offering choice, acknowledging people's feelings, and providing positive performance feedback have been found to enhance intrinsic motivation.

Deci and Ryan (1985) interpreted these results in terms of satisfaction versus thwarting of the basic needs for competence and autonomy. Specifically, people tend to interpret rewards, directives, deadlines, and threats as controllers of their behavior, which thwarts their need for autonomy; in contrast, people tend to experience choice and acknowledgment as support for their autonomy. Similarly, positive feedback tends to satisfy people's basic need for competence, whereas negative feedback tends to thwart that need.

Further studies examined the general interpersonal context or ambience of particular settings such as classrooms or workgroups. For example, investigators found that teachers who were more autonomy supportive (in contrast to being controlling) catalyzed their students' intrinsic motivation and desire for challenge, and that managers who supported their subordinates' autonomy promoted motivation and satisfaction on the job (Deci & Ryan, 2000). In fact, authority figures such as doctors, parents, and coaches have also been found to influence the motivation and behaviors of their patients, children, and athletes, depending on the degree to which they are autonomy supportive versus controlling.

Finally, Deci and Ryan (2000) pointed out that external events such as rewards, feedback, and deadlines can be interpreted differently by different people. That is, many external events such as rewards have both an aspect that *controls* behavior and one that conveys positive competence *information.* If the controlling aspect is more salient, it pressures people toward specific outcomes and undermines their intrinsic motivation. However, if the informational aspect is more salient, it affirms their competence and enhances their intrinsic motivation. Whether the controlling or informational aspect is more salient depends on both the situation and the person.

When the interpersonal context within which rewards or feedback are administered is generally autonomy supportive, the informational aspect of the rewards or feedback tends to be more salient. For example, studies have shown that, although monetary rewards typically diminish intrinsic motivation, they can maintain or enhance it if they are administered in an autonomy-supportive context.

In addition, some people, due to socialization, are inclined to experience events such as rewards and feedback as more informational, whereas others are inclined to ex-

perience them as more controlling. Thus, individual differences can lead different people to experience the same external event differently, so the event will have different effects on their intrinsic motivation (Deci & Ryan, 2000).

To summarize, intrinsic motivation flourishes when people are able to satisfy their needs for competence and autonomy while doing interesting tasks. Specific events in the interpersonal environment, such as the offer of rewards, the imposition of deadlines, and the provision of performance feedback can directly affect people's need satisfaction and, thus, their intrinsic motivation. The general interpersonal ambience can also impact people's need satisfaction and intrinsic motivation both directly and by influencing how they experience external events. Finally, people differ in their tendencies to interpret events and environments in ways that support versus thwart need satisfaction and intrinsic motivation.

Because intrinsic motivation is relevant in many walks of life and leads to more positive outcomes than extrinsic motivation, it seems important to support the autonomy and competence of our children, students, clients, employees, and patients.

INTROVERSION–EXTRAVERSION

Carl Jung coined the terms introversion and extraversion to refer to two different psychological types. By introversion, Jung meant a turning inward of the libido (psychic energy), whereas extraversion referred to a directing outward of the libido. Note that either term can be spelled with an "o" or an "a" (that is, either as above or as intraversion and extroversion). Although inconsistent, introversion and extraversion are the spellings used with the Myers–Briggs Type Indicator (MBTI), which is a popular personality assessment instrument based on Jung's type theory.

An introvert's mind, emotions, attention, and so forth are turned inward toward himself or herself. Jung believed that the introvert directs the libido inward because of inferiority feelings, an idea reminiscent of Alfred Adler. Particularly during stressful periods, introverts tend to withdraw into themselves, to avoid others, and to be self-absorbed. With a bent toward self-sufficiency, the introvert's essential stimulation is from within, from his or her inner world of thoughts and reflections. Introverts are frequently reserved and difficult to get to know, tend to bottle up their emotions, and need privacy.

In contrast, extraverts orient primarily to the outer world, focusing their perceptions and judgments on people and things. Extraverts draw energy from other people and external experiences; tend to express their emotions; need relationships more than privacy; and are usually friendly, talkative, and easy to get to know. Extraverts may seem shallow to introverts, whereas introverts may seem withdrawn to extraverts.

On the MBTI, the E-I or extraversion-introversion index is one of four dichotomous scales. The other three are sensing-intuition (S-N), thinking-feeling (T-F), and judgment-perception (J-P).

ISLAM AND PSYCHOLOGY

Introduction

There are two main ways of deciding the truth of an issue. We can believe something is true if we trust the source of the information. For example, Muslims believe that the Quran is divinely constructed. A second path to knowledge is through logical and critical reasoning of experienced phenomena. This is the method of scientific study on which psychology rests. This entry will focus on the primary focus of knowledge, the foundation on which knowledge is based, the methods for acquiring knowledge, the criteria for vali-

dating knowledge, and the potential for human change according to each approach.

Psychology examines the physical, cognitive, personality, social, emotional, and moral aspects of human development. Its emphasis is on the material aspects of the human being; the spiritual component, in contrast, is only marginally recognized.

In Islam, Allah created all things, including human beings. Allah created the universe alone and solely sustains and governs it. Human life has a divine and transcendental purpose because humans shall be resurrected in a Divine world (the Hereafter) and be made to account for their lives in this world. In the Islamic view, humans are creatures made of two components: matter and spirit. Humans should strive for the betterment of both in a balanced way. The Quran, which governs human lives, has been divinely formulated so that both components can be cared for in a balanced way. The Islamic Law (Shariah) and hadith (sayings of the prophet Muhammad [Peace Be Upon Him]) form documentation that governs the lives of Muslims everywhere.

Psychology

Source of Knowledge

In psychology as in all other behavioral and social sciences, the source of knowledge is confined to that ascertained by the human intellect and the senses. The primary focus of scientific knowledge is a study of reality, beginning with the material aspects of the universe.

Foundation of Investigation

Faith in reason and the experience of utilizing the scientific method forms the basis for psychological investigation. Psychology recognizes experimentation as the primary tool for verifying knowledge. The essence of logical positivism or empiricism is observation, measurement, and quantification of sense data. In undertaking this observation it is assumed that objective data are neutral and value-free. It is also assumed that the observer has shielded the methodology from the influence of all extraneous variables, confounding variables, personal attitudes, values, and biases by means of rigorous control mechanisms.

The natural and logical consequence of this methodology and its epistemological basis is reductionism. This has led to human behavior being reduced to the level of material bodies that can be studied within the confines of control and observation mechanisms.

Methods of Acquiring Knowledge

Psychological research tests hypothesize relationships and causal explanations. They evaluate the reliability, validity, and underlying factor structure of psychological measures. They also measure the degree of generalizability across samples.

Criteria for Validation

Psychological research is predicated on a particular set of assumptions, which are: (1) Order—scientists believe that events in the world are governed by deducible laws; (2) Determinism—order in events is likely to be causally related; (3) Empiricism—information should be gathered directly through sensory experience; and (4) Parsimony—economy of explanation.

Thus, psychological research is characterized by control of variables, operational definitions of the factors under study, and replicability of results.

Probability for Human Change

Psychological research leads to a range of views on the possibilities of personal development of human capacities. On the one hand, behavioral research suggests that altering stimulus–response relationships can alter behavioral patterns. This type of modification is used in a number of health domains (Sheridan & Radmacher, 1992). On the other hand, humanistic psychology advocates unlimited potential for personal control of individual development. In all cases individual progress is either facilitated or impeded by powerful biological, evolutionary, historical, and social forces.

Islam

Source of Knowledge

In Islam, the study of reality is considered to begin with the metaphysical or spiritual aspects of the universe. Principles of human development, human interaction, and human functioning in all aspects of life are derived initially from the Quran.

Foundation of Investigation

Faith is the belief in the authority of revelation. Belief in revelation as an infallible source of knowledge is an essential article of faith in Islam. This belief influences the search for knowledge and personal meaning in life. Faith in ultimate unknowns also forms part of the fabric of Muslim consciousness.

Methods of Acquiring Knowledge

Prayer is a fundamental pillar of Islam. Believers are enjoined to pray five times each day at set times. Prayer is considered to connect each human being with his/her Cre-

ator. This exercise is endorsed by Muslim scholars (Haeri, 1991) as enhancing discernment and understanding. Reading, listening, and understanding the Quran forms the crux of knowledge, since it is on the word of the Quran that all other knowledge is based. Discipline of material self or ego is a requirement for gaining knowledge and wisdom.

Criteria for Validation

The criteria for validation are personal and subjective interpretation of revealed word and associated texts, and consistency with prior interpretations and reflections.

Probability for Human Change

Muslims believe in a single, all-knowing, all-loving Creator who constructed human beings with powers and capacities that can be developed to an infinite extent. The purpose of human life is to fulfill one's potential. Each human being is gifted with certain specific virtues; however, each virtue if carried to its extreme becomes a vice. All life events serve to highlight human virtues. Ultimately, the purpose of life and life events is to bring each human being closer to Allah.

Conclusion

Psychology and Islam illustrate two main methods for obtaining knowledge: through trusting a divine revelation or through objective analysis of experienced phenomena. Both of these methods possess flaws. It is possible to read something from a credible source but misunderstand a particular issue. The possibility of error through personal experience is well documented; for example, optical illusions provide numerous examples of such errors (Gross & McIlveen, 1998). In addition, reason is capable of error, as evidenced by the fact that so many scientists have different explanations for the same set of data. For example, Eysenck (Eysenck Personality Questionnaire) and Cattell (Cattell 16PF) used the same method of factor analysis to arrive at two distinct measures of human personality (Carlson, Buskist, & Martin, 2000).

Finally, teachers of religion have different explanations for the same set of inspired text. For example, two different and unique explanations of personality have been derived from Islamic teachings: the Enneagram (Palmer, 1988) and the Three Levels of Self (Haeri, 1991).

As human life evolves so human understanding also evolves. Psychology and Islam are two world views which have led to two parallel paradigms for understanding human beings and the world in which we live. Each paradigm contributes a unique understanding to this issue. Whilst the language of the two paradigms may be different, their aims and objectives are the same. Although the two methodologies may provide different types of information, both are valid and both are necessary.

ISOMORPHISM

In psychology, the term isomorphism (from the Greek roots *iso* or "same" and *morph* or "form") is identified with Gestalt theory. Gestalt psychologists suggested that objective brain processes underlying and correlated with particular subjective experiences are isomorphic with, that is, have functionally the same structure as, those experiences. This proposal challenged early twentieth century mind/brain theories which viewed the brain as comprised of interconnected, insulated wires and switches rather than as a dynamic system of interdependent electrochemical processes.

One-to-one correspondence between isomorphic phenomena, as in mathematical set theory, is inconsistent with Gestalt theory. For example, two dotted circles, one composed of 30 dots along its circumference and another of 32 dots, are isomorphic in the Gestalt sense of having identical form; the number of dots composing each circle is immaterial as long as there are enough to specify the shape. The form or shape is crucial, not the number of "elements" it happens to have. Two circles, however many "elements" compose them, and irrespective of their color or size, are isomorphic simply because they both display the circular shape. Comparably, two squares are isomorphic even if they are of different sizes, brightnesses, or colors.

The first Gestalt reference to brain processes isomorphic with perceptual processes occurred in a 1912 paper by Max Wertheimer on apparent motion. It suggested brain processes that might correspond to the perception of motion when there is no motion in the physical stimulus. Assume, say, two one-inch vertical lines, x and y, separated horizontally by one inch. If line x is briefly exposed, then disappears, and an instant later line y is exposed, the observer may see not two stationary lines successively exposed, but a single line moving from location x to location y. If the sequence continues, so that right after line y disappears line x is exposed again, then line y reappears almost immedi-

ately after line x goes off, and so on, as long as the distance and time relations are appropriate, the perceived result is a single line moving back and forth. If the time between disappearance of one line and appearance of the other is too long, the observer experiences two successively exposed stationary lines in two different places; if the interval is too short (or if there is overlap in the time that both lines are exposed), the observer reports two stationary lines simultaneously exposed in two different places.

What happens in the brain when a single moving line is seen under these conditions? Wertheimer argued that particular parts of the visual cortex are activated when the observer sees the lines, one area of activation corresponding to line x, and another nearby corresponding to line y. Furthermore (and here Gestalt theory deviated from other mind/brain theories), when motion is perceived, there must be some kind of "short circuit" between the brain areas corresponding to line x and line y; this "short circuit" is the brain process isomorphic with the experience of a single moving line.

Wertheimer's hypothesis was elaborated by Kurt Koffka (in his 1935 book) and Wolfgang Köhler (in extensive perceptual experiments). Köhler and his collaborators derived predictions from the theory and validated these predictions experimentally. Köhler and Hans Wallach devoted a monograph (1944) to "figural after-effects," perceived distortions of figures generated by prolonged prior observation of other figures.

Assume, for example, that the perceived distance between two points in the visual field, x and y, is isomorphic with the electrical resistance between their corresponding locations in the visual cortex, X and Y. If the resistance is great, the brain processes X and Y are functionally far apart, and the perceived distance between corresponding points in the visual field, x and y, should be great; if the resistance is small, the perceived distance between their experienced isomorphic counterparts, x and y, should be small.

A change in resistance between two points in the visual cortex should result in a corresponding change in the isomorphic visual experience. Any continuing excitatory process in neural tissue generates a process that inhibits its own continuation. According to isomorphism theory, this inhibition is increased resistance. One way to enhance resistance between two points in the visual cortex, therefore, is excitation with an appropriate visual stimulus. Prolonged stimulation of the brain area corresponding to the space between two points in the visual field by a figure exposed visually in that space should increase resistance in the space, and the same two points in the visual field should therefore appear farther apart than before. Such distortions were indeed found in many of Köhler and Wallach's experiments.

These and further experiments (not only in vision but also in other modalities, such as kinesthesis) made the isomorphism theory widely discussed in the mid-twentieth century. In the 1950s, Karl Lashley and Roger Sperry (and their collaborators) challenged the theory experimentally. They incised the visual cortex of cats and monkeys and inserted insulating material into the cuts, or placed excellent electrical conductors on the surface of or into the animals' visual cortices. These disturbances in the brain's electrochemical characteristics, they argued, should destroy the performance of visual discriminations the animals had learned previously—if isomorphism theory was indeed correct. But these alterations in the brain produced no changes in the animals' ability to make visual discriminations they had learned previously. Köhler argued that field properties of local changes in the electrical characteristics of the brains should reorganize almost instantaneously, and hence no disturbance in visually guided performance would be expected. Neither Lashley nor Sperry rebutted this argument.

The theory was neither corroborated nor refuted by empirical data; neuropsychological researchers studied other issues. Nevertheless, Gestalt theory of physical processes in the brain that are functionally isomorphic with processes in subjective experience remains one significant effort to address the fundamental question of the mind–brain relation.

ITEM ANALYSIS

The major purpose of item analysis is to provide information on the extent to which the individual items making up

a test are functioning in a desired manner. This information can then be used to improve the reliability and validity of the test by editing or discarding poor items. An item analysis of an achievement test may also provide diagnostic information on what examinees know and do not know, serving as a basis for instructional planning and curriculum revision.

Item analysis information may be either rational (judgmental) or empirical (statistical). A rational item analysis entails careful inspection of each item to determine whether its content is accurate, congruent with the test specifications, free of cultural or other bias, and not contrary to standard item-writing guidelines. This approach is characteristic of item analyses of criterion-referenced achievement tests, but it can also be applied to norm-referenced tests.

Empirical item analysis involves the calculation of one or more statistical measures of item functioning, including an item difficulty index, an item discrimination (validity) index, and some measure of the functioning of distracters. The difficulty index (p) of an item is computed quite simply as the proportion of people tested who answer the item correctly. The optimum difficulty index varies with the purpose of the test and the type of item.

The procedure for determining an index of the ability of an item to discriminate among examinees attaining different scores on the criterion variable depends on the nature of the criterion and the type of test. The usual internal criteria for an achievement test are the total scores on the test itself, which are rank-ordered and divided into upper (U) and lower (L) groups. In the case of a norm-referenced test, these two groups usually consist of examinees in the top 27% and the bottom 27% of the distribution of total test scores. Then the discrimination index (D) for each item is computed as $D = p_U$ where p_U and p_L are the proportions of examinees in the top and bottom groups, respectively, who answer the item correctly. With an external criterion such as performance ratings or school marks, the item discrimination index is computed as the point-biserial correlation (r_{pb}) between item score (0 or 1) and scores on the criterion continuum. Obviously, the closer either D or r_{pb} is to 1.00, the more valid is the item as a discriminator between high and low scorers on the criterion. Depending on the size of the group of examinees on whom the indexes are computed, D or r_{pb} values as low as 0.20 may prove sufficient for retaining items. It should be noted, however, that selecting items on the basis of D will tend to yield an internally consistent, homogeneous test. In contrast, selecting items on the basis of p_{pb} will usually produce a less homogeneous test, but one with greater validity for predicting an external criterion.

Determination of the discriminative power of items on a criterion-referenced test involves a bit more work than was previously mentioned. W. J. Popham describes two procedures: (1) pretest–posttest differences and (2) uninstructed versus instructed group differences.

Although an item analysis of a multiple-choice test focuses on the difficulty and discrimination indexes of individual items, responses to the incorrect options (distracters) may also be examined. In general, each distracter should be equally attractive to examinees who do not know the answer to an item. Furthermore, the ratio of the number of examinees in the upper group (on the criterion) to the number of examinees in the lower group should be approximately equal for all distracters.

JAMES–LANGE THEORY OF EMOTIONS

The James–Lange theory of emotions has been the subject of considerable scientific debate since its publication by James in *Principles of Psychology* (1890). Portions of James's theory had been formulated by the Danish physiologist Lange in 1885. James combined his views with those of Lange, and credited Lange in the name of the theory. It offers a physiological explanation of the constitution, organization, and conditioning of the coarser emotions such as grief, fear, rage, and love in which "everyone recognizes strong organic reverberations," and the subtler emotions, or "those whose organic reverberations are less obvious and strong," such as moral, intellectual, and aesthetic feelings (James, 1890, p. 449).

The general causes of the emotions are assumed to be internal, physiological, nervous processes and not mental or psychological processes. The moods, affections, and emotions that persons experience are "constituted and made up of those bodily changes which we ordinarily call their expression or consequence" (James, 1890, p. 452). A purely disembodied emotion—for example, the emotion of fear without a quickened heartbeat, sharp breathing, or weakened limbs—would be a nonentity for this theory. The emotions are the result of organic changes that occur in the body as a reflex effect of an exciting object or fact confronting the person.

There are three factors in the sequence of an emotional experience: (1) the perception of an exciting fact or object; (2) a bodily expression such as weeping, striking out, or fleeing; and (3) a mental affection or emotion, such as feeling afraid or angry. Many theories of emotion, as well as common sense, place the bodily expressions of weeping, striking out, or fleeing after the emotion of anger or fear. The James–Lange theory alters this sequence, placing bodily expressions between the perception of the exciting fact and the emotion. In everyday terms, this means we cry and then feel sad rather than feeling sad and then crying. "The bodily changes follow directly the perception of the exciting fact . . . our feeling the same as they occur is the emotion" (James, 1890, p. 449; italics in original).

The debate that has surrounded the theory involves the relative importance of central nervous system processes and social environmental factors in the production of emotion (Pribram, 1981). Centralists (including James and Lange) have argued that there are discrete physiological changes for each emotion (Scheff, 1979; Kemper, 1978). Peripheralists argue that there is no discrete physiological change for each emotion (Cannon, 1927; Schachter & Singer, 1962); rather, there is only a bodily state of arousal modified by factors in the social environment. The experimental evidence is inconclusive (Kemper, 1978; Scheft, 1979).

Sartre, in *Sketch for a Theory of the Emotions* (1939), critically evaluated the James–Lange theory from a phenomenological perspective and rejected it on several grounds. First, behavior, physiological or expressive, is not emotion, nor is emotion the awareness of that behavior. Second, the body does not call out its own interpretations, which are given in the field of consciousness of the person. Third, the bodily disturbances present in emotion are disorders of the most ordinary kind and are not the causes of emotion. They ratify emotion's existence for the person and give emotion its believability, but are not its causes. Fourth, to have considered only the biological body independent of the lived body—and the person's consciousness of the body—as the source of emotion was to treat the body as a thing and to locate emotion in disorders of the body. Emotion as a part of the person's lived experiences in the life world has not been given adequate attention by either the centralist or the peripheralist followers of the James–Lange theory.

The James–Lange theory of emotions remains a viable theory today. The factors isolated by the theory are not disputed. Controversy remains over the ordering of the sequence of the factors and on the emphasis to be given to strictly physiological—as opposed to social and psychological—factors and processes (see Barbalet, 1998). However, the historical character of emotional experience suggests that cultural and structural factors strongly influence how emotions are felt and expressed (see Newton, 1998).

JUST NOTICEABLE DIFFERENCE (JND)

The concept of just noticeable difference (JND), also known as the difference threshold or difference limen (Latin for threshold), derives from early work in the area of classical psychophysics conducted in the mid-nineteenth century. This work was highlighted by the research of Ernst Weber (1795–1878), a German physiologist, whose experimental investigations focused on tactile stimulation and the determination of sensory thresholds. Weber's seminal work in this area was extended and elaborated on by Gustav Fechner (1801–1887), a professor of physics at the University of Leipzig (Germany), who coined the term *psychophysics* to refer to this area of experimental psychology. In 1860, Fechner published the first textbook on psychophysics (*Elemente der Psychophysik*) that highlighted the basic goals of this emerging discipline and the scientific methods that were to be employed to advance knowledge in this area (Watson, 1973).

A primary focus of classical psychophysics was on investigating the relationships between different types of physical stimuli and the sensations they evoked in human (and animal) subjects and in assessing the ultimate sensory capabilities of the organism. Of specific interest was determining thresholds for the detectability of stimuli. Much of the early research in this area focused on the determination of absolute thresholds. While investigators employed various experimental methods, depending on the specific nature of the research, subjects in such studies were typically presented with some stimulus (e.g., auditory, visual, tactile) of very low (and undetectable) intensity. This was then followed by a graded presentation of test stimuli, at increasing levels of stimulus intensity, with the subject's task being to indicate when they were able to detect the stimulus. Presentations of stimuli were continued until stimulus intensity was reached where the stimulus was reported as present. Since subjects in such studies were often found to be quite variable regarding the level of stimulus intensity required for detectability on different trials, experiments most often provided subjects with a number of stimulus presentation trials, with the subjects' absolute threshold being considered as that level of stimulation where the subject reported the stimulus as being present 50% of the time.

While experiments like these were designed to determine absolute thresholds (e.g., the smallest amount of stimulation required for detectability), other studies, specifically relevant to the present topic, focused on the issue of differential sensitivity or difference thresholds. Here the primary question was: To what extent must the intensity of one physical stimulus differ from that of a second physical stimulus for subjects to distinguish one from another? Studies of difference thresholds often employed experimental methods similar to those used in determining absolute thresholds. For example, subjects might be provided with a standard stimulus of a given weight, which could be used for purposes of comparison (the standard stimulus), and then be presented with a graded series of test stimuli which differed from the standard stimulus along the weight dimension. The subject's task would be to indicate whether a test stimulus was the same or heavier (or lighter depending on the nature of the specific study) than the standard stimulus. The primary focus of these studies was on determining the smallest increment in weight necessary for the subject to perceive the test stimulus as different from the standard stimulus (50% of the time). This threshold for the detection of differences in physical stimuli has been referred to by a variety of terms: difference threshold, difference or differential limen, least perceptible difference, or just noticeable difference. The term *just noticeable difference,* often abbreviated JND, is the one most widely accepted in the psychophysics literature. Formally, the JND can be defined as the magnitude of change in a stimulus necessary for it to be perceived as different from another stimulus, as the smallest detectable difference between two stimuli (Levine & Shefner, 1981).

Early work related to just noticeable differences in sensation was subsequently extended by attempts to characterize quantitatively the precise nature of the relationship between increases in the magnitude of physical stimuli and increases in just noticeable differences in detectability. Here, Weber's Law (which was actually popularized by Fechner) states that the amount of increase in stimulation that results in a just noticeable difference is a constant proportion of the standard stimulus. Thus a heavy stimulus must be increased by a larger increment in weight for one to notice a difference between the two objects than a lighter stimulus, where a smaller increment in weight may result in the detection of a difference.

It should be noted that remnants of this early interest in the concepts of absolute and difference thresholds are reflected in the psychological literature even today, although the concept of threshold has to some extent fallen into disrepute (apart from its value in assessing the capacity of sensory systems). This is due, in part, to the influence of contemporary cognitive psychology and current views of the individual as an active processor of information. Specifically, it would seem that notions of thresholds have been largely supplanted by concepts derived from signal detection theory (Green & Swets, 1974), where it is assumed that

detectability of stimuli is determined, not only by the sensory capacities of the individual, but also by the nature of the response criteria one adopts in responding to detectability tasks (Levine & Shefner, 1981).

K

KINDLING

Kindling is the development of full-blown seizures in response to repeated subthreshold stimulation of the brain. In the classical sense it involves intracerebral electrical stimulation of various areas of brain, most typically the amygdala, with electric currents that are below those required to produce a local afterdischarge (AD). However, with repeated stimulation, the afterdischarge threshold is decreased (brain excitability is increased) and ADs begin to emerge with increasing duration and complexity, and to spread to other areas of the brain. This process is accompanied by a behavior seizure stage progression through stage I (behavioral arrest), stage II (head nodding and chewing movements), stage III (unilateral forepaw clonus), stage IV (bilateral forepaw clonus with rearing), stage V (rearing and falling), and, following sufficient numbers of stimulation, stage VI (major motor seizures in the absence of exogenous electrophysiological stimulation—a true model of spontaneous epileptogenesis).

Kindling is obviously a model of seizure evolution and progression from triggered to spontaneous seizures. However, from the outset, Goddard and Douglas also described kindling as a model for neuronal learning and memory, as the brain was showing increasing and long-lasting increases in responsivity to repetition of the same stimulus over time. This was apparent using a variety of electrophysiological and behavioral end points, including lowering of the initial AD threshold, increasing AD duration and complexity, increasing spread to other areas of the brain, the concomitant progression of behavioral seizure stages evolution culminating in full-blown triggered seizures, and eventually spontaneous major motor seizures.

Much investigation has revealed a host of biochemical and structural changes associated with both the lasting kindled memory trace and shorter-lived compensatory or endogenous anticonvulsant mechanisms. Both of these processes involve a spatiotemporal evolving set of changes in first and second messenger systems, as well as in growth factors, immediate early genes (IEGs), and late effector genes (LEGs) ultimately associated with changes in neuronal excitability and the balance of neurotrophic and apoptotic processes. Thus, kindling appears to be a useful model for studying the complex cascade of changes in gene expression mediating biochemical and microstructural changes associated with neuronal learning and memory.

However, since seizure end points are not a common manifestation of most psychiatric illnesses, kindling must be considered a nonhomologous model and an analogy for related processes that are likely to occur in other neuroanatomical and biochemical systems that might be more pertinent to behavioral pathology short of a full-blown seizure end point. In this manner, the kindling analogy is used to help further characterize one course of the unipolar and bipolar illness which typically involves the occurrence of early stressors that are initially insufficient to precipitate a full-blown affective episode, but that, with stressor recurrence (parallel to repeated electrical stimulation kindling), may trigger an episode of depression or mania. With sufficient occurrence of these triggered affective episodes, they, too, may begin to occur in the absence of obvious psychosocial precipitants. The data of Kessing and Bolwig and colleagues have validated one of the many predictions based on the kindling model, in that the number of prior hospitalizations for depressive episodes is directly proportional to the vulnerability to a recurrence, as assessed by both incidence and latency to relapse.

Another potential use of the kindling model in conceptualizing some elements of neuropsychiatric disorders is in the realm of loss of therapeutic efficacy of a drug treatment via a tolerance mechanism. Initially, administration of anticonvulsants before each amygdala-kindled seizure is typically associated with a marked reduction or complete suppression of seizure manifestations, depending on the drug. However, with repeated drug administration prior to (but not after) each kindled stimulation, seizures eventually break through most pharmacological interventions based on pharmacodynamic (and not pharmacokinetic) alterations associated with the contingent tolerance.

Loss of efficacy via tolerance has increasingly been recognized as a problem in the treatment of a variety of neuropsychiatric illnesses, including trigeminal neuralgia, Panic Disorder, epilepsy, and the recurrent affective disorders. To the extent that there is parallelism between tolerance mechanisms across these diverse syndromes, manipulations that are found to slow the development of tolerance to the anticonvulsant effects of drugs on amygdala-kindled seizures may provide hints to some of the molecular mechanisms involved and the maneuvers that may be assessed and directly tested in the clinical situation.

The data from the preclinical anticonvulsant tolerance studies of Weiss and associates suggest that tolerance is

slowed by: use of higher rather than lower or only marginally effective doses; use of stable rather than escalating doses; use of higher potency drugs, such as valproate instead of carbamazepine or lamotrigine; initiating treatment early in the course of kindled seizure expression rather than late in its course; using combination strategies, such as combining carbamazepine and valproate at doses that for each alone would be associated with more rapid tolerance development.

In terms of approaching treatment when tolerance has already occurred, switching to drugs with different mechanisms of action may be most appropriate because these differently acting drugs are often not associated with cross-tolerance to the initial drug. When tolerance has occurred, returning to a previously effective agent after a period of time off that drug may also be helpful. Tolerance has been associated with the loss of selective endogenous anticonvulsant adaptations and with progression of the primary pathological processes of kindling. Hypothetically, a period of time off a drug would allow the endogenous compensatory adaptations to reemerge; this may be associated with renewed responsivity. Again, each of these potential approaches deserves consideration for its applicability to the clinical realm, and direct tests of the predictive validity of the model are needed. Some preliminary data are already supportive of some of the factors that might show loss of efficacy, such as the fact that lithium carbonate treatment instituted earlier in the course of bipolar illness is much more likely to be effective than when instituted later in the course of illness, after multiple episodes have occurred.

In summary, the development of kindled seizures to a previously subthreshold stimulation most clearly is a model of epileptogenesis, but may also be pertinent for considering molecular mechanisms and pharmacological interventions involved in the progression and treatment of a variety of other neuropsychiatric syndromes. Because the model is not behaviorally homologous for most of these syndromes, one must be particularly cautious about the direct inferences derived. The model would appear to be most useful in the area of conceptualization of mechanisms and interventions underlying syndrome progression and in its heuristic value toward new approaches to treatment and prevention.

KINSEY INSTITUTE

The Kinsey Institute for Research in Sex, Gender and Reproduction is a not-for-profit corporation associated with Indiana University, Bloomington. It is the oldest continuously operating institution in the United States, and perhaps the world, focusing on sexuality research; the archiving of art, literature, and scientific materials on sexuality; and public and academic sexuality education.

Alfred C. Kinsey and the Establishment of the Institute for Sex Research

The Institute for Sex Research was established in 1947 by Alfred C. Kinsey, Sc.D. (1894–1956), a professor of zoology and eminent entomologist, and Herman B. Wells, president of Indiana University (Christenson, 1971; Gathorne-Hardy, 1998; Pomeroy, 1972).

The Institute began with Kinsey's 1938 course on marriage, requested by the Association of Women Students (Christenson, 1971). The scant sexuality material then available was primarily clinical or based upon individual opinion and experience. Kinsey began questioning students about their sex lives to provide some empirical data for his course, ultimately developing a 350-question face-to-face interview, encoded to protect subjects' confidentiality. Eventually data were gathered from individuals around the United States. Kinsey conducted 8,000 of the more than 17,000 interviews collected by the Institute from 1938 to 1956 (Gebhard & Johnson, 1979). His application of social science techniques to the documentation of sexual behavior was revolutionary (Reinisch, 1998).

In 1940, Kinsey abandoned entomology to pursue sexuality research. By 1941 support from the National Research Council's Committee for Research in the Problems of Sex (funded by the Rockefeller Foundation) permitted assembly of a full-time research team: biologist Clyde Martin, 1941; psychologist Wardell Pomeroy, 1943; and anthropologist Paul Gebhard, 1946 (Reinisch & Harter, 1994).

Sexual Behavior in the Human Male (Kinsey, Pomeroy, & Martin, 1948), a dry, academic tome based upon 5,300 interviews with American men, was published and became an international bestseller, followed by *Sexual Behavior in the Human Female* (Kinsey, Pomeroy, Martin, & Gebhard, 1953), reporting on 5,940 American women. The two "Kinsey Reports" samples primarily included white, middle class, college educated individuals under 35 years of age. The data on many "taboo" sexual activities challenged contemporary views by revealing that many American men and women had engaged in these activities. These data were still relied upon in the mid-1980s when the emergence of AIDS demanded information on sexual behavior (Institute of Medicine/National Academy of Sciences, 1986).

The volume on female behavior caused a major furor. Congress targeted the Rockefeller Foundation for its funding of the Institute. In 1954 the Rockefeller Foundation withdrew funding of sex research. Proceeds from the "Kinsey Reports" were used for staff salaries. There were also legal expenses when the U.S. Customs Service seized explicit materials intended for the Institute's archives. Kinsey died at 62 of cardiac failure following pneumonia on August 25, 1956. The following year, the seizure battle was won by attorney Harriet Pilpell in the landmark *United States v. 31 Photographs.*

The Low-Profile 1960s and 1970s

Following Kinsey's death, Gebhard was chosen as director. For the next two decades, a low public profile was maintained. The focus was on publication of books from the database, and organizing the expanding collections. *Pregnancy, Birth, and Abortion* (Gebhard, Pomeroy, Martin, & Christenson, 1958), and *Sex Offenders: An Analysis of Types* (Gebhard, Gagnon, Pomeroy, & Christenson, 1965) were published as were books on erotic art and Victorian sexual culture. Reflecting staff interests, from the mid-1960s through the 1970s research related to the sociology of sexuality (Gagnon & Simon, 1973), sexual morality (Klassen, Williams, & Levitt, 1989) and psychosocial aspects of homosexuality (Bell & Weinberg, 1978). NIMH supported some library services and related scholarly materials were compiled.

Expansion of the Kinsey Institute for Research in Sex, Gender, and Reproduction

In 1981 the university mandated that the Institute be overseen by an independent board of trustees. Following Gebhard's retirement, in 1982 they appointed June Machover Reinisch, a developmental biopsychologist, as the third director, and research was expanded to include biomedical and psychobiological issues. In 1983, the Institute was renamed The Kinsey Institute for Research in Sex, Gender, and Reproduction. New research examined the consequences of maternal hormone and drug treatment during pregnancy on the psychosexual development of offspring (Reinisch, Mortensen, & Sanders, 1993). Sexual behavior research was maintained with studies on high-risk sexual behavior related to AIDS and other STDs (Reinisch, Hill, Sanders, & Ziemba-Davis, 1995). A series of research symposia resulted in the Kinsey Institute Series of volumes, including *Masculinity/Femininity* (Reinisch, Rosenblum, & Sanders, 1990), *Adolescence and Puberty* (Bancroft & Reinisch, 1990), *Homosexuality/Heterosexuality* (McWhirter, Sanders, & Reinisch, 1987), and *AIDS and Sex* (Voeller, Reinisch, & Gottlieb, 1990).

Based on the 1982 mandate of the trustees and the university to raise the Institute's public profile, the Institute began providing the public with scientific information on sex, gender, and reproduction (Reinisch, Sanders, Hill, & Ziemba-Davis, 1991). From 1984 to 1993, an internationally syndicated newspaper column, "The Kinsey Report," answered more than 2,900 questions sent by readers from around the world. The Institute produced its third bestseller and first book specifically designed for the general public, *The Kinsey Institute New Report on Sex* (Reinisch, with Beasley, 1990), which was also published in eight other languages.

Central to the Institute's work are its large collections of print items, private papers and diaries, photographs, fine art objects, artifacts, popular ephemera, data archives, films, and videotapes (Reinisch, 1993) encompassing human sexuality from all eras, regions, and cultures. Beginning in the mid-1980s, there was a threefold expansion and renovation of the library and archives facilities, the staff was tripled, patron workspace was expanded, and a new art gallery was installed. In addition, the first curators for the collections were appointed, and full-time technical and information services and inputting the library and archives catalogs on-line was begun.

Recent Years

In 1993, upon Reinisch's retirement, Stephanie A. Sanders, a psychologist and the Institute's associate director, was appointed interim director. The institute's educational, archival, and patron service programs grew, and studies on high-risk sexual behavior (Sanders & Reinisch, 1999) and the effects of prenatal drug exposure on adult behavior (Reinisch, Sanders, Mortensen, & Rubin, 1995) were completed. In 1995, John Bancroft, a British psychiatrist, was appointed as the fourth director. The Institute's research again changed direction, emphasizing sexual functioning and research methodology. The first Kinsey Institute-associated clinics addressing sexual and menstrual cycle–related problems were established. The symposium series was continued with *Researching Sexual Behavior: Methodological Issues* (Bancroft, 1997), *The Role of Theory in Sex Research* (Bancroft, 1999) and *Sexuality in Mid-Life and Beyond.* Renovation and expansion of the facilities continued, computerization of library catalogs was finished, and formal involvement in graduate and professional education was undertaken.

Surviving more than five often turbulent decades during which it was regularly under attack, The Kinsey Institute has remained the premiere academic institution focused on the interdisciplinary study of sex, gender, and reproduction. It continues to develop and maintain extraordinary archives for a wide variety of artistic, cultural, and scientific materials related to human sexuality that remain an unparalleled resource for future generations of scholars, students, and professionals.

LANGUAGE ACQUISITION

One of the most amazing human abilities is the mastery by infants of a complex linguistic system within a relatively short amount of time. In the first year of life, and even before, infants are learning important distinctions relevant to speech perception. For example, exposure to speech that occurs before birth enables newborns to recognize their mother's voice (DeCasper & Fifer, 1980), and to use prosodic and acoustic cues to recognize a particular story that was read to them while they were in the womb (DeCasper & Spence, 1986). After birth, infants show the ability to distinguish unfamiliar languages from each other based on rhythmic differences, and an increasing ability to distinguish their native language from other languages (Nazzi, Jusczyk, & Johnson, 2000). In the first half-year of life, infants are able to discriminate both phonetic contrasts that occur and those that do not occur in their native language, but before the first year is up, they generally lose the ability to distinguish contrasts not relevant to their native language (Werker & Tess, 1984). During the latter half of the first year, infants also demonstrate the ability to use different types of information—such as syllable stress, phonotactics (legal combinations of sounds within words), coarticulation, and the likelihood that certain syllables co-occur—to segment the continuous speech stream into words (Johnson & Jusczyk, 2001; Saffran, Aslin, & Newport, 1996).

Language production starts in the first year of life with cooing and babbling, which increases in complexity and mirrors the prosodic patterns of the native language. Children start producing words around their first birthday. Initially, productive vocabulary acquisition is slow. Then, at around 18 months, a burst in vocabulary acquisition occurs. In English, early words tend to be common nouns. With increasing vocabulary size, verbs and adjectives begin to increase in number, followed by growth in grammatical function words such as prepositions and articles (Bates et al., 1994). What words and word classes will be acquired early is probably a function of frequency and saliency in parental input, as well as their phonological or morphological complexity.

When acquiring vocabulary, children must determine the meaning of each new word. When an object is directly labeled, children tend to extend that label to other objects that are similar in shape, rather than to objects that perform the same function but have a different appearance (Graham, Williams, & Huber, 1999). When children are given a new word in the presence of multiple objects, they tend to assign it to a novel object or to an object or part of a known object for which they do not already have a name. There are multiple explanations for this tendency, among them simply that the children's attention is captured by novelty, and thus they associate the new word with what has captured their attention (Smith, Jones, & Landau, 1996).

Grammatically, children start off producing single word utterances. With increasing age, utterances increase in length (generally measured in terms of number of morphemes—i.e., meaningful units, rather than words per se) and sophistication. Early multiword speech tends to leave out unstressed and grammatical elements, although comprehension studies show that children do know what grammatical words are appropriate in a sentence frame (Gerken & McIntosh, 1993), and even children at the one-word stage have mastery of grammatical devices such as word order in comprehension (Hirsh-Pasek & Golinkoff, 1996). Grammatical sophistication increases with age, with predictable patterns of mastery on structures such as negation, questions, passives, and relative clauses.

Theoretical Orientations

Because language learning occurs so quickly, and with such apparent ease, researchers such as Chomsky and Fodor have proposed that language learning is fundamentally different from other cognitive processes and involves an innate, language-specific component. Much of this claim revolves around the mastery of the grammar. Theorists from this camp claim that the linguistic input that a child receives does not contain enough information to allow a child to correctly induce the grammatical structure of the language. Thus, some innate contribution is necessary to overcome this poverty of the stimulus. One particularly influential innate language-specific theory is parameter setting, which proposes that an infant is born with a set of switches, or parameters, that code all possible linguistic variation. These parameters begin with a default setting. Linguistic input then triggers these parameters to be set to the value appropriate for that language. Setting the parameter then grants mastery of particular syntactic structures of that language. This mastery may encompass other structures than that represented in the trigger input. Thus, through

the combination of the innate parameters and triggers from the linguistic input, grammatical mastery is achieved.

In contrast to the above viewpoint, other researchers believe that children bring general learning processes to language, and apply these to the input, which contains enough information for the child to figure out the grammar. Indeed, there is ample accumulating evidence that the linguistic input that children receive is not nearly as impoverished as innatists portray. For example, there are differences in phonetic and acoustic properties between content words and grammatical function words that may allow infants to distinguish between them (Morgan, Shi, & Allopenna, 1996). There is also a high, although imperfect, correlation between prosodic and syntactic units in speech, and during the first year of life, infants become sensitive to relevant prosodic cues (see Jusczyk, 1997). These prosodic cues may be exaggerated in the type of speech directed at infants. There is also evidence that children can use a general statistical learning mechanism to rapidly acquire knowledge about the speech stream. For example, with as little as two minutes of exposure to novel connected speech, infants can use co-occurrence regularities to parse the speech stream into words (Saffran, Aslin, & Newport, 1996) and to learn something about the underlying grammatical structure (Gomez & Gerken, 1999). Proponents of the general learning mechanism approach postulate that these and other types of information allow children to bootstrap up from the input to the grammar (see Hirsh-Pasek & Golinkoff, 1996).

LANGUAGE: ITS INTERGROUP PARAMETERS

Language is an integral element of most intergroup relations, as evidenced by the resurrection of Hebrew as a lingua franca in multicultural Israel, the role of French in Quebecois separation, and the revival of Catalan in Spain. But beyond nationalist and ethnic arenas, forms of language (e.g., dialect, nonverbals, and discourse) play key roles in virtually all intergroup situations—as evident in adolescents' distinctive speech styles, patronizing ways of addressing and referring to older adults and the physically challenged, expressions and tone of voice used among gay men, and so forth (see Clément, 1996). In fact, intergroup processes have become core foci in the social psychology of language, as witnessed by their frequent appearance across many different chapters of *The New Handbook of Language and Social Psychology* (Robinson & Giles, 2001).

Much of the research and theory devoted to these issues has its origins in the social identity theory (SIT) of intergroup relations (e.g., Tajfel & Turner, 1979). The latter emerged from European social psychologists' dissatisfaction with reductionist (predominantly North American) approaches that provided explanations of intergroup behavior couched in terms of individual psychology (e.g., frustration-aggression, belief dissimilarity). SIT, in contrast, articulated an explanation in terms of social beliefs about the contextual relations between groups. In particular, it highlighted a social motivation to create or maintain a positive social identity that is realized and constrained by people's beliefs about the place of their in-group in the status hierarchy. These beliefs concern the legitimacy and stability of intergroup status relations as well as beliefs about the feasibility, or lack thereof, of passing into another group.

Different combinations of these beliefs encourage different identity enhancement strategies.

One of the most developed products of this approach has, arguably, been its extension into the realm of language and intercultural communication (e.g., Gudykunst & Ting-Toomey, 1988), one that contributes enormously to our understanding of many language phenomena, including second language learning, code-switching, semilingualism, diglossia, patterns of language attitudes and language shifts, and so forth. An important theoretical force here has been ethnolinguistic identity theory, which has added further criteria (e.g., "group vitality") and brought into sharper focus the specific language strategies that might be used in intergroup settings (see Giles & Coupland, 1991). Group vitality articulates the ways that groups differ with respect to institutional support (e.g., via education and the media), demographic representation (e.g., numbers and concentration of group members), and status variables (e.g., economic control and a historic sense of in-group pride). The more group members perceive their group to possess these facets of vitality, the more likely they are to engage in activities designed to maintain their so-called "psycholinguistic distinctiveness" (via language, dialect, specialized jargon, slang, code words, etc.). Certain caveats notwithstanding, research around the globe has shown that groups possessing high perceived vitality prosper, while those that lack such vitality integrate with dominant groups or die out.

While ethnolinguistic identity theory describes the wider macrosocial processes that frame language use, communication accommodation theory describes the accomplishment of these identity enhancement strategies within microsocial contexts (see Giles & Coupland, 1991). Broadly, language can be used to draw out similarities with an interlocutor (called "convergence"), or it can be used to maintain or enhance social distance (called "divergence"). In an interpersonal context, convergence is assumed to reflect an interlocutor's motive of wanting to be liked; convergence indicates similarity to the recipient which, in turn, can foster social attraction. In intergroup contexts, "upward" convergence by a minority group speaker to the dominant group's language can be found when people are not particularly invested in their group identity; when group boundaries are thought to be surmountable; and when the status distinction is considered to be legitimate and stable. Such convergences would be even more likely if such speakers also construed their group vitality to be relatively low.

At other times, and sometimes even in the same intergroup context, "downward" divergence (i.e., the maintenance or accentuation of a subordinate group's language forms, such as with the Hawaiian language movement) can be found in individuals who are strongly committed to their group; who consider the social boundaries between their group and the dominant group to be impermeable; who construe their group's vitality to be relatively high; and who believe their status inequality vis á vis the outgroup is unstable and illegitimate.

By considering these and other background conditions, we can see how views about bilingualism—as being additive to or detracting from one or another group's identity—can evolve in a society. Indeed, immigrants' supposed "failure" to acquire near-native proficiency in their host community's language can, from an intergroup perspective, be reinterpreted as the immigrants' successful retention of their own group's language in the face of a significant threat to its survival in that milieu. Such a position has profound implications for second language pedagogy and the kinds of social factors deemed necessary to address in teaching people bilingual skills.

As alluded to earlier, this general theoretical backdrop has been confirmed, extended, and applied in a number of intergroup contexts, notably between genders, socioeconomic brackets, different generations, and those of differing physical capacities, as well as in the strategic use of language in sustaining, legitimizing, and subverting social power (see Harwood & Giles, in press). Future work in the study of "intergroup language"—that which is regulated by individuals' awareness of their memberships in various relevant social groups (Hindu, gang member, physician, and so forth)—is likely to move beyond SIT by taking into account theoretical developments in self-categorization theory (Turner, Hogg, Oakes, Reicher, & Wetherell, 1987). This replaces the social motivational mechanism in SIT with a social-cognitive mechanism: group behavior is driven by a search for a maximally meaningful identity that seeks to determine how individuals fit into the world. They achieve this by identifying with groups that simultaneously maximize within-group similarities and between-group differences. Self-categorization theory can lead, potentially, to language-based theories of leadership emergence, stereotyping, social influence, and social attraction. What is more, the same mechanism might be integrated into ethnolinguistic identity and communication accommodation theories, thereby providing a more parsimonious account of language shifts and macrosocial conditions that increases our understanding of who in an particular social group uses which language strategies, addressing also questions of how, when, with what outcomes, and why.

LATE-LIFE FORGETTING

There is considerable public concern that memory loss signals the beginning of Alzheimer's disease or senility. Early diagnosis, combined with intervention and family support, can assist older adults with memory loss to function and to manage life on a daily basis in the least restrictive setting.

The first task for the health professional faced by a patient concerned about memory loss is to ascertain whether the symptoms are indicative of dementia or whether they are the result of normal decline in cognitive abilities associated with the aging process. Even if there is a diagnosis of dementia (defined by the American Psychiatric Association as a loss of intellectual abilities of sufficient severity to interfere with social or occupational functioning), it is important to determine whether the dementia is reversible or not. If the cause is determined promptly, some dementias are reversible, because an almost limitless array of diseases and behavioral disorders can result in a dementing process. Muriel Lezak (1995) points out that memory loss serves as a starting point for differentiating individuals with normal forgetting from those who might warrant a diagnosis of dementia.

Two types of memory impairments are described by Asenath LaRue (1982) to distinguish between normal and nonnormal forgetting. Originally, these were labeled *benign senescent forgetfulness* and *malignant senescent forgetfulness.* Benign forgetfulness was characterized by memory failures limited to relatively unimportant facts but included the ability to recall these at a later time. Most of the forgotten aspects were part of the remote rather than the recent past, and the individual was usually aware of the memory loss and could compensate for it. In some ways, this type of forgetting is not unlike the absentminded professor stereotype. In contrast, malignant forgetfulness of old age included distortion of memories, reduced retention time, and difficulties in remembering recent events and experiences. In addition, disorientation to place, time, and eventually, person also occurred. On the face of it, this seemed to be a straightforward distinction between types of forgetfulness. However, critics have speculated whether benign and malignant senescent forgetfulness are points on a continuum rather than separate conditions.

There have been a number of attempts to define changes in memory associated with normal aging. A National Institute of Mental Health work group was established in 1986 to study and encourage research and communication in this area. This work group published diagnostic criteria for what they termed age-associated memory impairment (AAMI). The criteria for AAMI required the presence of memory complaints based on a gradual onset of memory loss in adults 50 years and older functioning within an acceptable intellectual level (specifically defined by the criteria). To meet the criteria of AAMI, individuals must perform 1 standard deviation (SD) below the average established for younger adults on tests of recent memory. In addition, a number of criteria exclude an individual from meeting the AAMI category. These include the presence of dementia, alcohol dependence, depression, certain neurological disorders, and/or other medical disorders. Current use of psychotropic drugs also would disqualify an individual from meeting the diagnostic criteria. AAMI, it was argued, was designed to describe older adults who have memory problems but who do not suffer from a neurological impairment. It was assumed that AAMI is a normal consequence of aging in a proportion of older individuals.

Richard C. Blackford and Asenath LaRue (1989) took some issue with the measurement aspects of AAMI. They recommended that there should be two categories within AAMI: age-consistent memory impairment and late-life forgetfulness. The criteria for age-consistent memory impairment include performance on 75% of memory tests used that are within +1 SD of the mean established for that participant's age.

The criteria for late-life forgetting requires performance on 50% or more of the tests given that are within 1 to 2 SD below the mean established for that age. The exclusion criteria for each of these subcategories is somewhat similar to those stated previously for age-associated memory impairments. All these categories apply to individuals between the ages of 50 to 79, but exclude individuals 80 and above.

Glenn Smith and others (1991) studied age-associated memory impairment, age-consistent memory impairment, and late-life forgetting by testing 523 cognitively normal older adults living in the community. The researchers did not seek out individuals who complained of memory problems. In fact, they specifically selected participants who did not present memory complaints. After excluding those participants who did not meet criteria (e.g., those who were taking psychotropic medications or had histories of alcohol abuse or who had medical, neurological, or other relevant disorders), they found that 98% of members in one group and 77% of members in another group met criteria for age-

associated memory impairments as suggested by the National Institute of Mental Health. The researchers concluded that age-related changes in memory should avoid the implication of disability suggested by the term *impairment.* They believe that a better term would be *age-associated memory decline.* They also recommended that more effort be expended to develop normative data for individuals of advanced age, including the old-old. Finally, the researchers recommended that a specific memory battery be used rather than permitting researchers to select from a range of testing instruments. Glenn Smith and colleagues (1991) also point out that there is wide variability in the diagnosis of early or probable dementia, and the use of the term *impairment* suggests abnormality and disease. They counter that the true meaning of scoring 1 SD below that of younger individuals in decline of memory functions has not been determined. In the meantime, it might be best not to label such declines as pathological. More recent developments include the use of the term *mild cognitive decline* (MCI), which is viewed as a transitional state between normal aging and Alzheimer's disease—recognizing, however, that many individuals with MCI will not develop Alzheimer's disease. Howard Chertkow (2002) suggests that mild cognitive impairment may be the stage in which preventive therapies are most useful, since he estimates that 19 to 50% of individuals with mild cognitive impairments progress to dementia over three years.

LATE-LIFE PSYCHOSIS

The number of elderly persons with psychosis has risen in tandem with the growth of the geriatric population. The predisposing factors include comorbid illnesses, pharmacokinetic alterations, cortical neuron loss, neurochemical changes, social isolation, sensory deficits, cognitive changes, polypharmacy, premorbid personalities, and female gender.

Diagnoses associated with psychosis in the elderly include Delirium, Schizophrenia, Delusional Disorder, Mood Disorder, Dementia, Substance Abuse, medical conditions, neurological conditions, and Substance-Induced Psychotic Disorder.

Cognitive impairment in the elderly, including organic psychosis, has an estimated prevalence rate of 16.8% to 23%. In a study of patients with Alzheimer's disease, 63% developed psychosis. The prevalence rate of delirium in hospitalized elderly is reported to be 11% to 24%.

Structural abnormalities, including white matter hyperintensities and focal brain disease, have been reported in elderly patients with psychotic disorders. Subjects with late onset psychotic disorders have abnormal brain imaging studies, and half had white matter lesions and/or lacunar infarctions.

Delirium

Delirium is an acute state characterized by changes in cognition and consciousness, often accompanied by visual hallucinations and paranoid delusions. Delirium may be superimposed on other neuropsychiatric conditions. Clouded consciousness, poor attention span, and a fluctuating course during the day are features that help in the diagnosis. Early recognition and treatment of the cause are important to reduce the high morbidity and mortality rates associated with this diagnosis. Common causes of delirium include infections; drugs, especially anticholinergics; electrolyte imbalance; arrhythmia; and myocardial infarction. Other causes include transient ischemic attacks, cerebrovascular accidents, structural brain lesions, and withdrawal from prescription medications and substances of potential abuse. Disruption of cerebral metabolism and neurotransmission, particularly of dopamine and GABA pathways, have been implicated in the pathophysiology of delirium. Persistent cognitive deficits may reflect a concurrent dementing illness.

Schizophrenia

Schizophrenia may continue into old age or, rarely, its first episode may occur in patients older than 45. Approximately 15% of all patients with schizophrenia may have onset of symptoms after the age of 45. There are some differences between Late Onset and Early Onset Schizophrenia (LOS and EOS). LOS is more common in women, has fewer negative symptoms, and tends to respond to lower doses of antipsychotic medication than EOS. MRI study of the size of thalami found them to be larger in LOS than EOS.

Symptoms of EOS tend to become less severe with age. Both positive and negative symptoms improve in about 20%

of patients, remain relatively unchanged in 60% of patients, and worsen in only 20% of patients.

Delusional Disorder

As per *DSM-IV,* patients with Delusional Disorder reveal persistent delusions without prominent hallucinations in the absence of Dementia, Schizophrenia, or Mood Disorders. The delusions are nonbizarre and usually circumscribed. Patients are generally resistant to treatment.

Mood Disorder with Psychosis

Mania and depression in the elderly can be associated with psychotic symptoms such as delusions and hallucinations. Elderly patients with psychotic depression are at increased risk for relapse and have more persistent symptoms, suicide attempts, hospitalizations, comorbidity, and financial dependency.

Dementia with Psychosis

Psychotic symptoms can occur in dementia secondary to various etiologies. Alzheimer's disease is the most common cause of dementia, and more than 50% of patients manifest psychotic symptoms during the course of the illness.

Detailed discussion of late life psychotic disorder due to medical or neurological conditions, substance abuse, or prescription drugs is beyond the scope of this brief article and may be found elsewhere.

Treatment of Late-Life Psychosis

A thorough psychiatric and medical assessment is essential before initiation of treatment. Social, behavioral, and environmental interventions should be considered before pharmacotherapy. Antipsychotic drugs, cholinesterase inhibitors, electroconvulsive therapy, mood stabilizers, benzodiazepines, and buspirone are the most commonly used medications.

Pharmacokinetic and pharmacodynamic factors, comorbid medical illnesses, and concurrent medications increase side effects and drug interactions in this population. The geriatric psychopharmacology maxim "start low and go slow" should be followed in the use of these medications. The appropriate starting dose of antipsychotics in the elderly is 25% of the adult dose and daily maintenance dose is 30 to 50%. Antipsychotic medications in the elderly can require 6 weeks or longer for optimum therapeutic effects. Patients with Dementia generally require smaller doses of antipsychotics than patients with Schizophrenia.

Conventional Antipsychotics. The use of conventional antipsychotics is limited because of their increased potential for serious side effects. The advantages include the availability of parenteral preparation for rapid control of agitation and long-acting, injectable preparations for haloperidol and fluphenazine.

Atypical Antipsychotics. The atypical agents are as efficacious in reducing positive symptoms, more efficacious in reducing negative symptoms, and have a much safer side effect profile.

Clozapine has moderate to good efficacy and very low rate of extrapyramidal symptoms (EPS), but has significant other side effects including delirium, somnolence, orthostasis, agranulocytosis, and cardiac effects. Its use requires regular monitoring every 2 weeks for adverse effects on the white blood cell count. Clozapine is the only antipsychotic medication with demonstrated efficacy in the treatment of refractory Schizophrenia.

Risperidone is the most widely studied atypical agent used in treating the elderly. The most frequent side effects reported include sedation, dose dependent EPS, dizziness, and postural hypotension. The advantages include negligible anticholinergic effects, low incidence of EPS and tardive dyskinesia (TD) (at low doses), and efficacy for positive and negative symptoms.

Olanzapine is increasingly being used in the elderly. The side effects include sedation, weight gain, anticholinergic effects, dizziness, and orthostasis. The advantages include low incidence of EPS and good effect on positive and negative symptoms.

Quetiapine is the least studied atypical agent used in treating the elderly. The common adverse effects include somnolence, dizziness, and postural hypotension. Advantages include negligible EPS and minimal anticholinergic effects, with good effectiveness on positive and negative symptoms.

Conclusion

The new atypical antipsychotic agents offer significant advantages over conventional agents in the treatment of psychosis in the elderly. Antipsychotic drugs form part of a comprehensive treatment plan which should include psychosocial, behavioral, and environmental interventions in the management of late-life psychosis.

LATENT INHIBITION

Latent inhibition (LI) is demonstrated when a previously exposed, unattended stimulus is less effective in a new learning situation than a novel stimulus. The term *latent inhibition* dates back to Lubow and Moore (1959), who intended to design a classical conditioning analog of latent learning. As such, the LI effect was "latent" in that it was not exhibited in the stimulus preexposure phase, but rather in the subsequent test phase. "Inhibition" simply reflected the fact that the effect was manifest as a *retardation* of learning. Since that first demonstration, there have been hundreds of LI-related experiments. LI is extremely robust, appearing in all mammalian species that have been tested and across many different learning paradigms.

The ubiquitous nature of LI suggests some adaptive advantages. Indeed, LI appears to protect the organism from associating irrelevant stimuli with other events. It helps to partition the important from the unimportant, and thus to economize on processing capacity by selectively biasing the

organism to more fully process new inputs as opposed to old, inconsequential ones.

Although the term *latent inhibition* is descriptive, the phenomenon has been subject to a number of theoretical interpretations. One class of theories holds that inconsequential stimulus preexposure results in reduced *associability* for that stimulus as compared to a novel stimulus. The loss of associability has been attributed to a variety of mechanisms that reduce attention (see Lubow, 1989 for a review), which then must be reacquired in order for learning to proceed normally.

Alternatively, it has been proposed that LI is a result of *retrieval failure* rather than acquisition failure. Such a hypothesis suggests that following stimulus preexposure, the acquisition of the new association to the old stimulus proceeds normally. However, in the test stage, two competing associations may be retrieved, an earlier stimulus–no consequence association from the preexposure stage and/or the stimulus–unconditioned stimulus association of the acquisition stage. In normal LI, the nonpreexposed group performs better than the preexposed group because there is only the second association to be retrieved, whereas the preexposed group performs poorly because both the first and second associations, which are in competition, are retrieved.

Among those variables that consistently have been shown to modulate the size of the LI effect, and perhaps the most important theoretically is that of context. In virtually all LI studies, the context, unless specifically an experimental variable, remains the same in the stimulus preexposure and test phases. However, if context is changed from the preexposure to the test phase, then LI is severely attenuated. In addition: (1) For context and stimulus preexposure to be effective in producing LI, the two must be preexposed conjointly; (2) Context preexposure after preexposure of the stimulus in that same context (context extinction procedure) has little or no effect on LI; and (3) Preexposure of the context prior to stimulus preexposure in the same context increases the magnitude of LI.

The various stimulus preexposure–context effects have been used to develop a theory of the conditioning of inattention and its modulation to account for both LI in normals and its reduction in schizophrenics. The theory states that normal LI is manifest when the preexposure context reappears in test and sets the occasion for eliciting the stimulus–no consequence association that was acquired during preexposure. As such, the context limits the access of the previously exposed irrelevant stimulus to working memory. In addition, it has been proposed that in schizophrenia, there is a breakdown in the relationship between the preexposed stimulus and the context, such that the context no longer sets the occasion for the expression of the stimulus–no consequence association. Consequently, working memory is inundated with experimentally familiar but phenomenally novel stimuli, each competing for the limited resources required for efficient information processing. This description fits well with the symptoms of schizophrenia, particularly high distractibility, as well as with research findings.

The assumption that the same attentional process that produces LI in normal subjects is dysfunctional in schizophrenics has stimulated considerable research. Evidence to support this contention comes from several sources, including the parallel effects of dopamine activity associated with schizophrenia and with LI. There is much data that indicate that dopamine agonists and antagonists modulate LI in rats and in normal humans. Dopamine agonists, such as amphetamine, abolish LI, while dopamine antagonists, such as haloperidol and other neuroleptics, produce a super-LI effect. In addition, manipulations of putative dopamine pathways in the brain have the expected effects on LI. Thus, hippocampal and septal lesions interfere with the development of LI, as do lesions of the nucleus accumbens (for reviews, see Gray, 1998; Weiner & Feldon, 1997). With human subjects, there is some evidence that non-medicated schizophrenics show reduced LI compared to medicated schizophrenics and normals, while there are no differences in the amount of LI in the latter two groups. Finally, symptomatically normal subjects who score high on psychotic-prone or schizotypal scales also exhibit reduced LI compared to low psychotic-prone/low schizotypal subjects (for a review, see Lubow & Gewirtz, 1995).

In addition to LI illustrating a fundamental strategy of information processing and providing a useful tool for examining attentional dysfunctions in pathological groups, LI has also been used to explain why certain therapies, such as alcohol aversion treatments, are not as effective as might be expected. On the other hand, LI procedures may be useful in counteracting some of the undesirable side effects that frequently accompany radiation and chemotherapies for cancer, such as food aversion. Finally, LI research has suggested techniques that may be efficacious in the prophylactic treatment of certain fears and phobias (for a review of the practical applications of LI, see Lubow, 1997).

In summary, the basic LI phenomenon represents some output of a selective attention process that results in learning to ignore irrelevant stimuli. It has become an important tool for understanding information processing in general, as well as attentional dysfunctions, and it has implications for a variety of practical problems.

LEARNED HELPLESSNESS

Learned helplessness was discovered when researchers immobilized a dog and exposed it to electric shocks that could be neither avoided nor escaped. Twenty-four hours later, the dog was placed in a situation in which electric shock could be terminated by a simple response. The dog did not make this response; instead, it just sat passively. This behavior was in marked contrast to dogs in a control group that reacted vigorously to the shock and learned to turn it off.

These investigators proposed that the dog had learned to be helpless. When originally exposed to uncontrollable shock, it learned that nothing it did mattered. Shocks came and went independently of behavior. This learning of response-outcome independence was represented as an expectation of future helplessness that was generalized to new situations to produce motivational, cognitive, and emotional deficits. These deficits following uncontrollability have come to be known as the *learned helplessness phenomenon,* and their cognitive explanation as the *learned helplessness model.*

Much of the early interest in learned helplessness stemmed from its clash with traditional stimulus-response theories of learning. Alternative accounts of learned helplessness were proposed by theorists who saw no need to invoke mentalistic constructs, and these alternatives emphasized an incompatible motor response learned when animals were first exposed to uncontrollability. This response was presumably generalized to the second situation, where it interfered with performance at the test task.

Steven Maier and Martin Seligman (1976) conducted a series of studies testing the learned helplessness model and the incompatible motor response alternative. The most compelling argument for the cognitive account comes from the *triadic design,* a three-group experimental paradigm that differentiates uncontrollability from trauma. Animals in one group are exposed to shock that they are able to terminate by making some response. Animals in a second group are yoked to those in the first group, exposed to the identical shocks; the only difference is that animals in the first group control their outcome whereas those in the second do not. Animals in a third group are exposed to no shock at all. All animals are then given the same test task. Animals with control over the initial shocks typically show no helplessness when tested. They act just like animals with no prior exposure to shock. Animals without control become helpless.

Also supporting a cognitive interpretation of helplessness are studies showing that an animal can be "immunized" against the effects of uncontrollability by first exposing it to controllable events. Presumably, the animal learns during immunization that events can be controlled, and this expectation is sustained during exposure to uncontrollable events, precluding helplessness. Other studies show that learned helplessness deficits can be undone by exposing a helpless animal to the contingency between behavior and outcome. The animal is forced to make an appropriate response to the test task, by pushing or pulling it into action. After several such trials, the animal responds on its own. Again, the presumed process at work is cognitive. The animal's expectation of response-outcome independence is challenged during the "therapy" experience, and learning occurs.

Psychologists interested in human problems were quick to see the parallels between learned helplessness as produced in the laboratory and maladaptive passivity as it exists in the real world. Thus began several lines of research looking at learned helplessness in people. First, helplessness in people was produced in the laboratory much as it was in animals, by exposing them to uncontrollable events and seeing the effects on their motivation, cognition, and emotion. Unsolvable problems were usually substituted for uncontrollable electric shocks, but the critical aspects of the phenomenon remained: Following uncontrollability, people show a variety of deficits similar to those observed among animals. Second, researchers proposed various failures of adaptation as analogous to learned helplessness and investigated the similarity between these failures and helplessness. Especially popular was Seligman's (1975) proposal that depression and learned helplessness shared critical features: causes, symptoms, consequences, treatments, and preventions.

It soon became clear that the original helplessness model was an oversimplification when applied to people, failing to account for the range of reactions that people display following uncontrollability. Some people indeed showed pervasive deficits, as the model hypothesized, that were general across time and situation, whereas others did not. Further, failures of adaptation that the learned helplessness model was supposed to explain, such as depression, were sometimes characterized by a striking loss of self-esteem, about which the model was silent.

In an attempt to resolve these discrepancies, Lyn Abramson, Martin Seligman, and John Teasdale (1978) reformulated the helplessness model as it applied to people.

The contrary findings could be explained by proposing that when people encounter an uncontrollable (bad) event, they ask themselves why it happened. Their answer sets the parameters for the helplessness that follows. If their causal attribution is stable ("it's going to last forever"), then induced helplessness is long-lasting. If their causal attribution is global ("it's going to undermine everything"), then subsequent helplessness is manifest across a variety of situations. Finally, if the causal attribution is internal ("it's all my fault"), the individual's self-esteem drops following uncontrollability. These hypotheses comprise the *attributional reformulation* of helplessness theory.

In some cases, the situation itself provides the explanation. In other cases, the person relies on a habitual way of making sense of events that occur, what is called *explanatory style.* Explanatory style is therefore a distal influence on helplessness and the failures of adaptation that involve helplessness. Explanatory style has been studied in its own right, and it has an array of correlates. People who explain bad events with internal, stable, and global causes show passivity; poor problem-solving; depression; anxiety; failure in academic, athletic, and vocational realms; social estrangement; morbidity; and mortality. Explanatory style can be highly stable, sometimes over decades. The self-fulfilling nature of explanatory style—and helplessness per se—explains this stability. At the same time, explanatory style can and does change in response to ongoing life events. Cognitive therapy, for example, can move explanatory style in an optimistic direction.

LEARNING CURVES

Progress in learning reflects itself in a number of different ways: increases in the rate, probability of occurrence, speed and vigor of responding, decreases in latency (time required to initiate a response), time required to complete a task, and number of errors committed in doing so. These changes in performance are frequently presented in one of a variety of forms called *learning curves,* in which the baseline is most often the number of practice trials but occasionally is time. The vertical axis represents one of the measures just mentioned.

The different measures of learning behave in different ways if the learning involves practice. Amplitude, probability of occurrence, speed of responding, and rate curves show an increase; latencies and other time measures decrease. Probability and percentage of response curves often show a double inflection. Because conditioned responses sometimes do not appear until after several reinforcements, the first portion of the curve may be flat. This portion is followed by a positively accelerated increase, which is soon replaced by a negatively accelerated one as a maximum is approached.

Most learning curves are for groups of subjects, rather than for individuals. For many purposes this creates a problem, especially in experiments where subjects are run to some criterion such as 100% conditioning in a block of trials. Different subjects will take different numbers of trials to reach the criterion, and it becomes difficult to find a baseline against which to plot the response measures to represent the course of acquisition. One solution to this problem is in the use of the *Vincent curve.* The total number of trials required for each subject to reach the criterion is divided into fractional parts such as tenths, and measures are plotted for these portions. This method makes it possible to combine data for subjects whose performances differ widely.

Unfortunately, this and other procedures for combining data may distort the picture of acquisition presented by the learning curve. For one thing, the typical performance of individual subjects in a learning experiment is irregular, showing chance upward and downward excursions. To select the first point at which a subject reaches some arbitrary level as the criterion of learning is very often to stop the learning session at a point that is accidentally high. This fact accounts for at least some of the end spurts obtained in Vincentized data. These appear as rather sudden increases in the final segment of practice. It now seems that they often occur as *criterion artifacts,* because the experiment is terminated after a series of unusually good performances.

Greg A. Kimble

LEARNING OUTCOMES, I

The primary means of indicating that learning has occurred is to show that some newly appearing human performances are possible, when required by appropriate cir-

cumstances. The inferences that can be made from these changes in performance are to the effect that individuals have acquired some new entities in their long-term memory store—entities not present before the learning occurred. The outcomes of learning, then, are neural states that persist over considerable periods of time, as shown by tests of retention. Because the effects of these states are to make individuals persistently capable of exhibiting particular kinds of performance, it is reasonable to think of them as *learned capabilities.*

Differences in Learned Capabilities

From a broad and practical view, it is of considerable help in defining the boundaries of knowledge in the field of human learning to distinguish some principal types of learning outcomes. The outcomes clearly differ from one another in the performances they make possible. They differ, too, in important respects in the specific conditions optimal for their learning. Presumably, they also differ in the nature of the cognitive structures that represent them in long-term memory.

Varieties of Learning Outcomes

On the basis of the criteria previously described, five kinds of learned capabilities may be distinguished.

1. *Verbal knowledge (declarative knowledge).* This kind of knowledge ranges from single names and labels through isolated "facts" to bodies of organized information. The kind of performance made possible by such knowledge is *stating* (declaring) orally, in writing, or in some other medium.
2. *Intellectual skills (procedural knowledge).* These capabilities enable the individual, by manipulation of symbols, to demonstrate the application of concepts and rules to specific instances. The distinction between "knowing that" (declarative knowledge) and "knowing how" (procedural knowledge) was given prominence by the philosopher Gilbert Ryle.
3. *Cognitive strategies.* These are skills used to direct and influence cognitive processes such as attending, perceiving, encoding, retrieving, and thinking. Cognitive strategies of problem solving were studied in concept identification tasks by Bruner, Goodnow, and Austin. More recently, the effects of cognitive strategies in controlling or modifying other cognitive processes of learning and memory, such as attention, encoding, and retrieval, have been studied extensively. When taught to and deliberately employed by learners, such strategies constitute a major aspect of what is called *metacognition.*
4. *Attitudes.* This fourth kind of learning outcome is generally considered to possess affective as well as cognitive memory components. Attitudes are learned states that influence the choices of personal action the individual makes toward persons, objects, or events.
5. *Motor skills.* Learning outcomes sometimes consist of actions accomplished by smoothly timed muscular movements called motor skills. Most motor skills involve performing procedures, sometimes lengthy ones. The procedure itself may be simple or complex and has been called the *executive subroutine.* This procedure may be learned separately or as an early stage of acquiring the motor skill. Learning the motor skill itself is a matter of acquiring increasing smoothness and precise timing of muscular movement. Often, the executive subroutine has the function of molding part skills into a total skill.

Relation of Learning Outcomes to the School Curriculum

The outcomes of school learning are usually stated as curricula, composed of subject matter content such as reading, writing, mathematics, science, history, and so forth. Each of these subjects usually includes more than one category of learning outcome. Thus, arithmetic is made up largely of intellectual skills, but includes also some essential verbal knowledge about situations in which quantitative concepts are applicable.

Clearly, the five kinds of learning outcomes—verbal knowledge, intellectual skills, cognitive strategies, attitudes, and motor skills—cut across the traditional subject matters of the school curriculum. Each subject area typically seeks to establish more than one kind of capability in students. To achieve optimally effective learning, as well as optimally efficient management of learning, the design of instruction in each subject matter field must take into account the different requirements of each type of learning outcome.

Relation to Other Taxonomies

Perhaps the best-known taxonomy of learning objectives is that proposed by Bloom and his coworkers. Although the categories described in this article have been independently derived from a different theoretical base, they show great similarity to Bloom's topics and are in most respects compatible. The three major strands of the Bloom taxonomy are the *cognitive domain,* the *affective domain,* and the *psychomotor domain.*

Conditions of Learning Favorable for Each Outcome

From learning research and theory, it is possible to specify with reasonable assurance the conditions favorable to the learning that lead to each outcome. These conditions differ somewhat in each case, and the existence of these differ-

ences provides a major reason for distinguishing among learning outcomes in designing instruction.

Verbal Knowledge

A number of lines of evidence support the theoretical contention that *prior knowledge* is of great assistance to the learning of new knowledge. The precise nature of the relation between old knowledge and new—in the sense that the former aids the learning and retention of the latter—is presently a matter of active investigation. A second factor of importance for optimal learning is the *organization* of the instructional communication (or other stimulus), which affects the process of encoding. The inclusion of *contextual* cues at the time new knowledge is learned is another condition favoring retention of that knowledge.

Intellectual Skill

The primary condition affecting the learning of intellectual skills is the *accessibility of prerequisite skills.* In contrast to the case of verbal knowledge, these subordinate skills are related to the new skill to be learned as components. The implication is that instruction for optimal learning requires the precise identification of these prerequisite skills, by methods of task analysis. A second condition affecting the retention of intellectual skills is *spaced review* and *practice.* Many basic skills prerequisite to skilled performance in reading, writing, and arithmetic apparently need to be practiced to the level of automaticity.

Cognitive Strategies

Because cognitive strategies are a type of skill, one might expect optimal conditions for learning to be similar to those for intellectual skills. In a sense this is the case: Prerequisite skills must be mastered for cognitive strategies to be learned. However, the prerequisite skills of strategies are often extremely simple, well practiced, and readily accessible. Many strategies of attending, learning, retrieving, and problem solving can be conveyed (or retrieved) by means of a *brief verbal communication.* Some strategies of problem solving, however, do not appear to persist unless practiced in a variety of contexts. Recognition of this fact leads the designers of instruction to suggest that students be given frequent opportunities to solve novel problems.

Attitudes

Although attitudes may be acquired in numerous ways from the experiences of living, it appears that the most dependable deliberate arrangement of conditions for optimal learning involves the technique of *human modeling.* The human model can be an actual human being, a pictured person, or even a printed description. It is most desirable for the model to be perceived by the learners as admirable, credible, and powerful. The procedure leading to attitude learning or modification, according to Bandura, includes two steps: The model (1) communicates or demonstrates the choice of action reflecting the target attitude, and (2) is seen to experience satisfaction and be rewarded for this action choice (vicarious reinforcement). Subsequently, additional strength of attitude can presumably be attained when the learners themselves are reinforced for their choices of personal action.

Motor Skills

The learning of a motor skill often begins, as Fitts and Posner point out, with the acquisition of a cognitive component (actually, an intellectual skill) called the *executive subroutine.* This is the procedural part of the skill. Sometimes separate practice is undertaken of *part skills.* The various components of a complex motor skill come together in *practice of the total skill.* Indeed, it is practice and practice alone that brings attainment of the smoothly timed action that is recognized as a motor skill.

Robert M. Gagné

LEARNING OUTCOMES, II

The term *outcome* broadly refers to what an individual has learned as a result of having been engaged in a learning activity of some kind. Within different research perspectives, however, the term takes on a more precise meaning that varies in crucial ways from one perspective to another. These variations, and the assumptions that underlie them, can be examined in relation to *traditional, neo-Piagetian,* and *phenomenographic* research perspectives.

The Traditional Perspective and Its Shortcomings

Within traditional research on learning the outcome of learning is neutral in content and quantitative in character. The experimental procedure commonly followed is to investigate the effect of one or more independent variables on a dependent variable specified in advance. If the resultant findings are in accord with hypotheses derived from a theory, the validity of that theory has been supported.

In all these experiments the dependent variable is in a quantitative form that makes the content of learning invisible; of no interest in itself, it is there simply because there cannot be any learning without a content of some kind. These two aspects of the conventional paradigm of research on learning—the quantitative nature of the dependent variable and the instrumental character of the content of learning—are logically related to a third and superordinate aspect: the aim of arriving at general (and

content-neutral) statements about learning, applicable to any kind of subject matter.

Whether this approach is a reasonable basis for psychological research on learning, its relevance to the educational context is questionable. A school is not concerned only with students' acquisition of information and skills: One of its main tasks—indeed, many would argue, *the* main task—is to shape and change pupils' ways of thinking. Thus, schooling should facilitate a transition from commonsense notions of the surrounding world to conceptions more in line with scientific ways of thinking.

The history of science clearly shows that the conceptual frameworks of every scientific discipline have repeatedly gone through radical qualitative shifts, while research on cognitive development points to restructurings of the maturing child's reality that are similar, even if less obvious in their everyday context. To describe outcomes of learning in this particular sense, it is necessary to discover what qualitatively different conceptions of the content of learning are apparent after the teaching/learning process has occurred. To describe the preconditions of learning, it is necessary to find out what qualitatively different preconceived ideas the learners have about the content they will encounter.

In this alternative interpretation, then, *outcomes of learning* are defined as the qualitatively different ways of understanding the content of learning. In what follows, two alternative approaches to this problem will first be examined in turn and then discussed in relation to each other.

A Neo-Piagetian Approach

If learning is conceptualized as was previously described, the distinction commonly made between learning and development becomes somewhat difficult to maintain. Transitions between qualitatively different ways of thinking represent the well-known Piagetian view of cognitive development. It seems easy to understand that the most widespread approach to the description of outcomes of learning has been based on the extension of Piagetian thinking into various subject-matter domains.

It is important to note that these researchers consider their work as studies less of learning than of development. Levels of thinking in different content areas were conceptualized as resulting from the application of general operatory structures to those domains. This was held to be true in both an epistemological and an ontological sense. The former refers to the expectation that the researcher will be able to discern the levels of thinking in a particular content domain by applying the description of the general Piagetian stages to that domain. In contrast, if students exhibit a certain level of thinking in relation to a particular content, they are interpreted as having applied the general operatory structures characteristic for the corresponding stage of development to that particular content.

Research has, however, cast doubt on the validity of this line of reasoning. Flavell and Hundeide, among others, have summarized many investigations challenging the notion of stages and content-free mental structures.

It is nonetheless important to acknowledge what has been achieved. The assumption of stage-related mental structures may not be warranted, in light of the empirical evidence now available of variation in performance on tasks that differ in content and context but are structurally similar. Yet the differences in thinking described are of great interest in themselves, whether the differences are stable across varying contexts and subject matter or not.

Biggs and Collis consider the different levels of thinking identified in these domains as outcomes of learning rather than development-related phenomena. The name they gave to their model of description—SOLO (Structure of the Observed Learning Outcomes)—reflects this. According to these authors, mastering a skill or a knowledge domain can be viewed as a miniature development that can be described in terms of transitions between qualitatively different levels of thinking.

If a group of students who have been dealing with a certain content is observed, it is likely that different students will have advanced to different points. The qualitatively different levels of thinking observed will then appear as qualitative differences (between individuals) in the outcome of learning.

The five general levels of thinking described by Biggs and Collis are as follows:

1. *Prestructural.* A nonexistent, irrelevant, or otherwise inadequate attempt to learn a component is made.
2. *Unistructural.* One relevant component is acquired.
3. *Multistructural.* Several relevant components are acquired, but additively and independently of each other.
4. *Relational.* The components become functionally or conceptually interdependent.
5. *Extended abstract.* The integrated components become part of a more general case, which in fact forms a new mode.

These five levels of thinking correspond to Collis's modification of Piaget's stages: preoperational, early concrete, middle concrete, concrete generalization (originally, early formal), and formal. Biggs and Collis argue that the characteristics that a certain individual's thinking exhibits on various tasks may vary widely, but that the characteristics themselves (in the sense of categories of description) are applicable to the various tasks regardless of content.

A Phenomenographic Approach

The third perspective originates mainly from the work of a Swedish research group. Marton has argued that description of the qualitatively different ways in which people experience, conceptualize, perceive, and understand various

aspects of the world around them should be considered as an autonomous scientific specialization, termed *phenomenography*. The arguments for seeing this as an autonomous field of concern are twofold. First, categories of description that characterize people's notions about reality are considered to be of interest in themselves—not the least in educational contexts. Second, such categories cannot be derived from more general properties of the human mind, but must be investigated in their own right.

The relevance of phenomenography to research on learning stems from the conceptualization of learning as a change between qualitatively different ways of understanding a phenomenon or an aspect of reality as contrasted with, for instance, a conceptualization of learning as a memorization of something read or as an acquisition of facts, details, and so on. Because phenomenography is concerned with discerning the different ways in which we understand aspects of the world around us, learning is seen as a transition between phenomenographic categories.

In general, phenomenography offers an alternative way of describing both effects and preconditions of learning and teaching. It aims at making explicit *what* (conception) is changed to *what* (conception). By pinpointing levels of conceptions of fundamental aspects of reality, it identifies a possible dimension of change, and by revealing the everyday ideas about the content of learning and teaching that the students bring with them to the school situation, it increases the likelihood of change.

Similarities and Differences Between the Two Alternative Approaches

As pointed out earlier, within both a neo-Piagetian and a phenomenographic approach, learning is conceptualized as a transition between qualitatively different forms of thought and is thus seen as a miniature development. In a normal school situation it seems quite reasonable to expect that, at the time of a particular observation, different students have advanced to different levels. The outcome of learning will thus be described in terms of qualitative differences. Furthermore, in relation to both ways of describing qualitative differences in the outcome of learning, some correlates have been found in the differing ways in which students set about the learning tasks that account for those differences. Biggs has identified three independent dimensions in study process: utilizing, internalizing, and achieving. The students' ways of studying were found to be highly correlated with learning outcomes.

In spite of these obvious similarities, there is an important difference between the two sets of studies that has to do with the role of content. Biggs and Collis use a general structural model as a point of departure. As the actual content varies in different instances, the realization of categories also will, of course, vary on a concrete level. The structural properties are considered to remain the same, however. Furthermore, they form an explicit hierarchy, as the notion of levels would suggest.

The phenomenographic approach is radically content-oriented because deriving categories of description in relation to various contents of learning is considered to be the main task. The different categories may or may not form a hierarchy in a particular case (of content).

In the SOLO model the description of outcomes of learning takes the form of the application of the general model to new content domains, while in phenomenography each new phenomenon, concept, or principle studied requires the discovery of the qualitatively different ways in which that particular phenomenon, concept, or principle is thought about, experienced, or "lived."

F. I. Marton

LEARNING THEORIES

The field of learning studies how experience produces long-lasting effects in the way that behavior changes with variation in the environment. Learning theory consists of principles that summarize the processes that produce these changes. Learning principles are based upon experimental observations, commonly from the laboratory. Learning theory has two main purposes: (1) to explain existing laboratory findings and aid the discovery of new findings, and (2) to provide plausible accounts of more complex phenomena that occur outside of the laboratory, where well-controlled observations are impossible to obtain. Although learning theory is based on laboratory observations (i.e., experiments), its principles are applicable to general societal concerns such as educational practice and the alleviation of dysfunctional behavior. Laboratory studies of learning usually involve observations of nonhuman animals. The experience of nonhumans can be better controlled, which allows the findings to be attributed to events that take place within the experiment. Although the learning theorist remains open to the possibility that some principles may be unique to humans, biology and neuroscience suggest that basic learning principles are common to most species with which we share an extensive evolutionary history and a common set of physiological processes.

The effect of the *ancestral* environment on behavior is most fundamentally understood through Darwin's principle of natural selection. The central goal of the learning theorist is to develop an account of the effects of the *individual* environment that is as powerful as the principle of natural selection. The search for this principle—a principle of reinforcement—began with the research of Edward L. Thorndike (1932) and Ivan P. Pavlov (1927), and was most explicitly continued in the work of B. F. Skinner (1938) and

Clark L. Hull (1943). Two related experimental procedures are used in the study of reinforcement—classical (or Pavlovian) conditioning and operant (or instrumental) conditioning. Both procedures present the learner with a stimulus that already elicits behavior, generally as a result of natural selection, as with the elicitation of salivation by food. In the classical procedure, the eliciting stimulus is presented after some relatively neutral stimulus, such as a tone or light. In the operant procedure, the eliciting stimulus is presented after some relatively arbitrary behavior, such as pressing a lever. In both procedures, the eliciting stimulus brings about a change in the way the environment affects behavior on future occasions. For example, in the classical procedure the tone comes to evoke salivation, whereas in the operant procedure, the sight of the lever comes to evoke lever pressing (as well as salivation). When these experiences change behavior, the eliciting stimulus is said to act as a *reinforcer.*

What conditions must be present for a stimulus to act as a reinforcer? Experimental work has identified two conditions. The first condition is *contiguity,* and was discovered with both the classical and operant procedures. If the eliciting stimulus is to serve as a reinforcer, it must occur within a very brief time interval (a matter of seconds at most) after the event upon which it is dependent—a stimulus in the classical procedure or a response in the operant procedure (Gormezano & Kehoe, 1981). If the putative reinforcer is delayed, whatever other stimuli or responses may have intervened are affected. The second condition is *discrepancy,* which was not identified until the mid-twentieth century (Kamin, 1969). Laboratory research indicates that not only must a brief interval elapse before the reinforcer occurs; but also the reinforcer must evoke a *change* in ongoing behavior. As examples, in the classical procedure, a stimulus followed by food, and in the operant procedure, lever pressing followed by food do not promote learning if another stimulus already evokes salivation at the moment when food appears. The learning mechanism is engaged only when a would-be reinforcer evokes a change in ongoing behavior. Natural selection has ensured that learning occurs only when the learner is "surprised" to receive the reinforcer.

Although general agreement exists concerning the two conditions needed for learning, learning theories differ among themselves as to how best to state the principle of reinforcement. Two main approaches are considered here—*associationism* and *biobehaviorism.* In the associationist approach, behavioral observations are used to infer the processes that underlie the observed changes in behavior. These inferred processes are called *associations,* following the tradition of British empiricist philosophy. For example, if salivation becomes more likely in the presence of a tone in the classical procedure, a strong tone-food association is inferred. Or, if lever pressing becomes more likely in the operant procedure, a strong lever press-food association is inferred. The nature of the underlying association is often based on tests conducted after original learning. For example, experiments have shown that if lever pressing is followed by food, and then food is separately paired with a noxious stimulus, lever pressing declines in strength. The decline occurs even though lever pressing itself never preceded the noxious stimulus. On the basis of these behavioral observations, the theorist infers that a response-reinforcer association (i.e., a lever press-food association) was formed during the original operant procedure, and that this association was weakened, or devalued, when food was paired with the noxious stimulus in a classical procedure (cf. Colwill & Rescorla, 1986). Historically, most learning theories have been of the inferred-process type, ranging from the earlier theories of Edward Tolman and Clark Hull (see Estes et al., 1954 for a review of earlier theories) to the later theories of William Estes and of Robert Rescorla and Alan Wagner (1972).

In a biobehavioral approach to learning theory, the reinforcement principle is initially stated in terms of behavioral observations only. For example, the discrepancy requirement is defined as a difference between the strength of the response elicited by the reinforcing stimulus (e.g., salivation elicited by food) and the strength of that same response at the moment before the reinforcing stimulus is presented. By contrast, the associationist approach defines the discrepancy requirement as the difference between the maximum associative strength supportable by the reinforcer and the associative strength of prevailing stimuli with that reinforcer. The first definition of discrepancy is stated in behavioral terms; the second in terms of inferred associationist processes. When learning theory is restricted to behavioral terms, it follows the approach of B. F. Skinner, known as *behavior analysis.* When behavior analysis is supplemented by observations at the level of neuroscience, it constitutes a biobehavioral approach. For example, a learned reinforcer—such as a tone that has previously been paired with food—may evoke little behavior. Hence, there is no discrepancy that is readily measurable at the behavioral level. In such cases, a biobehavioral approach points to the observation at the neural level that learned reinforcers can activate the same brain structures as food (Shultz, 1997). Thus, the biobehavioral approach is a synthesis of behavior analysis and neuroscience.

Theories of learning increasingly integrate behavioral and neuroscientific research, which satisfies the need to specify the processes that mediate environment-behavior relations without an appeal to inferred processes. Given the rapid advances in neuroscience, reliance on inferences from behavior is being replaced by direct observations of the neural processes that implement learning. The major remaining task for learning theory is to demonstrate that the principle of reinforcement is sufficiently powerful to provide a compelling account of complex human behavior—memory, language, problem solving, and the like (cf. Donahoe & Palmer, 1994).

LEISURE COUNSELING

Leisure counseling emerged as a specialty within the counseling profession only during the 1970s, with its own literature, professional journals, and practitioners. It as yet lacks a substantive theoretical base and solid research support for its concepts, although these are beginning to appear. Leisure counseling has been the province of two professional groups, those concerned with leisure studies (including therapeutic recreation) and those concerned with counseling. There has been a tendency to perceive leisure behavior as a matter of choosing activities, rather than looking at leisure from the point of view of the psychological *meaning* of these activities for the individual.

The recent interest in leisure counseling can in part be traced to increasing affluence in Western Europe and North America, and the decline of the Protestant ethic as a source of individual and societal values. Whereas in previous times of scarcity, work was extolled and leisure denigrated, we are now increasingly turning to leisure as a major source of life satisfaction and meaning. This is especially true for those individuals whose work often lacks meaning and intrinsic interest. Unfortunately, it is precisely those people whose leisure activities are often lacking in variety, challenge, and meaning.

Definitions of Leisure

At least four categories of leisure definitions have appeared in the literature, although they overlap conceptually. *Residual definitions* view leisure as what one does in the time left over after the necessary activities of life have been accomplished. *Activity-related definitions* define leisure by the type of activity in which one engages. Certain activities are considered to be leisure and others defined as work, regardless of the context in which they occur.

Work-related definitions of leisure reflect the value structure of the Protestant work ethic. The first has been called *complementary,* or *spillover,* in which the nature of one's leisure activities is similar to one's work activities. The second type has been called *supplemental* and refers to leisure activities intentionally chosen to be quite different from those typically engaged in while at work. *Compensatory* leisure refers to activities that are designed to reduce or eliminate stresses or tensions that the individual experiences in daily life.

Psychological definitions of leisure tend to stress the meaning of the leisure experience for the individual, rather than the type of activity engaged in or its relation to some other activity. J. Neulinger defines leisure as a state of mind—being at peace with oneself and what one is doing. His concept of leisure revolves around two bipolar constructs: freedom versus constraint and intrinsic versus extrinsic motivation.

Needs and Motives for Leisure

Many personality theorists of diverse orientations note that a basic human task is the development of a sense of competence, mastery, or self-efficacy. It has been found that individuals choose those activities in which they perceive themselves to be competent because participation in such activities elevates one's sense of competence and enhances one's sense of freedom. Furthermore, learning new leisure skills (assuming minimal and increasing competency) enhances one's self-concept, whereas practicing already learned skills only maintains one's existing self-concept.

Other needs and motives for leisure have also been found. People appear to be motivated by a need for optimal arousal and incongruity, or what one might call "novelty

value." The level of optimal arousal will, of course, differ from individual to individual, but participation in leisure activities can help satisfy this need for everyone. In addition, leisure is valued to the extent that it provides positive interpersonal involvement.

Emerging Leisure Paradigms

Several comprehensive treatments of the psychological nature of leisure have recently appeared. McDowell has argued that the leisure experience is characteristic of "right-brain thinking," while work consciousness is characteristic of "left-brain thinking." In addition, he has developed the concept of leisure well-being, which he defines as "an esthetic, enjoyable, satisfying, healthful and dynamic leisure-style." McDowell suggests that leisure well-being involves four key components of self-care: coping, awareness–understanding, knowledge, and assertion.

Seppo E. Iso-Ahola considers the four most important determinants of the perception of an experience as leisure to be (in order of importance) (1) perceived freedom to engage in the activity, (2) intrinsic motivation to engage in the activity, (3) whether the activity is related to daily work, and (4) whether the activity is oriented toward final goals or instrumental goals. There is some evidence that, given an already high level of interest in an activity, expected external rewards for engaging in that activity can actually *reduce* the individual's later engagement in it.

The phenomenon of leisure has also been examined from an attributional point of view. Attribution refers to the process by which a person assigns causes to events, behaviors, and outcomes in an attempt to construct causal meaning out of situations. Attributions have been found to have three dimensions: internality–externality (whether the cause resides within or outside the individual); stability–instability (whether the cause is stable over time); and globality–specificity (whether the cause is common to many situations). The positive relationship between perceived freedom and internal causality is quite high; therefore, individuals tend to define leisure as those activities attributed to internal stable causes.

An internal-unstable attribution for the leisure activity would be made when the individual is engaging in new activities in which competence is sporadic. It would be especially useful in this situation to assist the person in attributing success to internal factors, rather than external factors, so that participation in the activity is maintained and is not labeled as "work."

The global–specific dimension refers to attributions of leisure competence (or incompetence) of oneself in relation to perceived competence of others.

Models of Leisure Counseling

Numerous models of leisure counseling have been proposed in the last few years, organized by Tinsley and Tinsley into three categories: (1) leisure guidance, (2) leisure decision making, and (3) leisure counseling. Leisure guidance models stress information-giving techniques that focus on assisting clients in choosing appropriate leisure activities that are interesting to them. In leisure decision-making models, the focus is still on assisting the client in choosing appropriate leisure activities, but there is a greater use of the client–counselor relationship as part of the leisure counseling interaction, as well as a greater awareness and use of the decision-making process. Leisure counseling involves a holistic focus on the total individual and the establishment of a facilitative counseling relationship.

Goals of Leisure Counseling

A primary goal of leisure counseling is to provide for an increase in the clients' perceived competence by engaging in activities at which they can succeed. A second goal is to provide for the clients' increased sense of freedom by engaging in freely chosen, competence-enhancing activities.

Another goal of leisure counseling is to increase an individual's level of optimal arousal and incongruity, an area in which many people are sorely lacking. In principle, this can be accomplished by increasing the variety, challenge, and complexity in one's leisure experience.

Leisure activities can also serve as a trial preparation for subsequent activities: Numerous people have turned hobbies into satisfying occupations. Leisure activities can also satisfy needs that cannot be met through other activities (e.g., work).

LEWINSOHN'S MODEL OF DEPRESSION

Lewinsohn's original model of depression (Lewinsohn, Weinstein, & Shaw, 1969) emphasized a "reduced rate of response-contingent reinforcement" as a critical antecedent for depression. Reinforcement was defined by the quality of the patient's interactions with his or her environment. Those person-environment interactions with positive outcomes constitute positive reinforcement. Such interactions strengthen the person's behavior. The term "contingent" refers to the temporal relationship between a behavior and its consequences. The reinforcement must follow the behavior. The model assumed that the behavior of depressed persons does not lead to positive reinforcement to a degree sufficient to maintain their behavior. Hence, depressed persons find it difficult to initiate or maintain their behavior, and become increasingly passive. The low rate of positive reinforcement was also assumed to cause the dysphoric feelings.

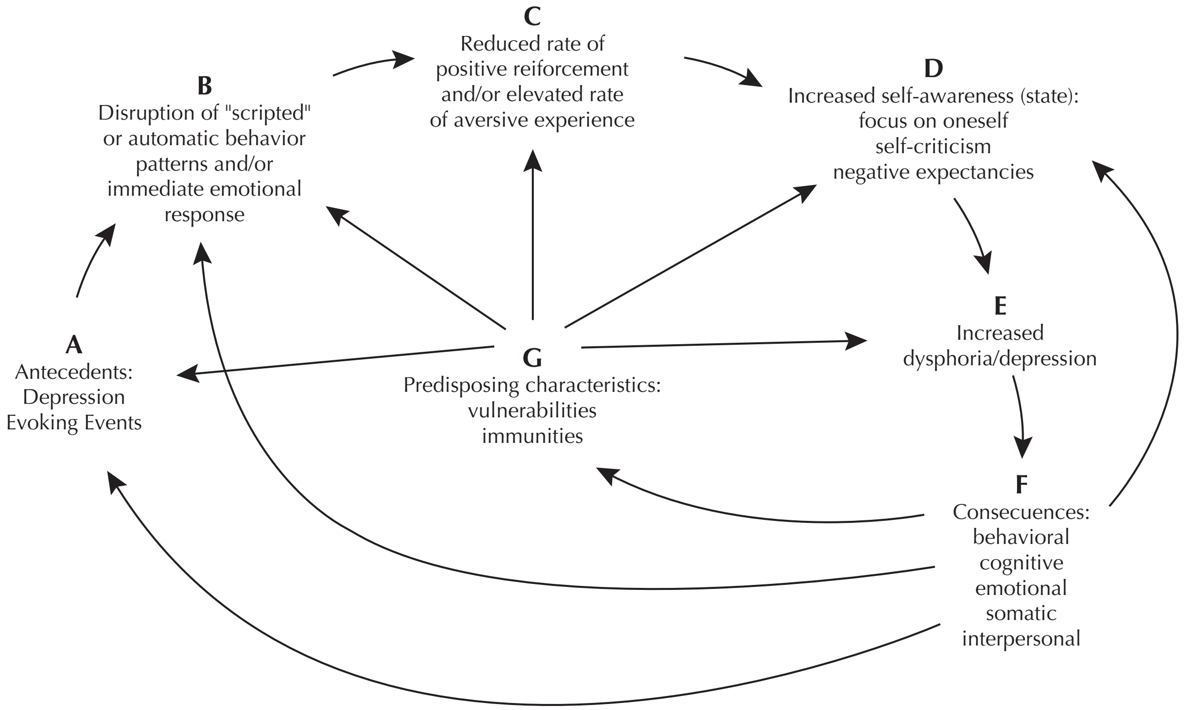

Figure 1. Lewinsohn's model of depression.

A low rate of response-contingent positive reinforcement may occur because (1) events that are contingent on behavior may not be reinforcing; (2) events that are reinforcing may become unavailable; or (3) reinforcers may be available but because of lack of the required skills, the individual is unable to elicit them.

An important supplement to the behavioral position was that the social environment provides reinforcement in the form of sympathy, interest, and concern for depressive behaviors. These reinforcements are typically provided by a small segment of the depressed person's social environment (e.g., the immediate family). Since most people in the depressed person's environment (and eventually even his family) find these behaviors aversive, they will avoid the person as much as possible, thus decreasing the depressed person's rate of receiving positive reinforcement and further accentuating the depression.

A number of different environmental events (e.g., the death of a loved one, separation, rejection, poverty, misfortune) and organismic states and traits (e.g., lack of social skill, physical disease) were presumed to be causally related to a low state of positive reinforcement. Social skill was seen as an area of deficit especially important in the development of depressive behaviors.

On the basis of empirical studies (Grosscup & Lewinsohn, 1980; Lewinsohn & Amenson, 1978; Lewinsohn, Lobitz, & Wilson, 1973; Lewinsohn, Mermelstein, Alexander, & MacPhillamy, 1985; Lewinsohn & Talkington, 1979; Lewinsohn, Youngren, & Grosscup, 1979) the theory was expanded to incorporate a relationship between aversive events and depression. Specifically, it was hypothesized that depressed individuals are more sensitive, experience a greater number of aversive events, and are less skillful in terminating aversive events.

In 1985, Lewinsohn, Hoberman, Teri, and Hautzinger broadened the scope of the previously described theoretical efforts and proposed an "integrative" theory of depression, which is represented in Figure 1.

The earlier model did not assign a causal role to depressotypic cognitions, assuming them to be consequences of the depressed state. The "integrative" theory views the occurrence of depression as a product of environmental as well as dispositional factors. The chain of events leading to the occurrence of depression is postulated to begin with the occurrence of an evoking event or antecedent (A). The occurrence of antecedents is assumed to initiate the depressogenic process to the extent that the antecedents disrupt substantial, important, and relatively automatic behavior patterns of an individual (B). Such disruptions, and the emotional upset they typically engender, are assumed to be related to the occurrence of depression to the extent that they lead to a reduction of positive reinforcement or to an elevated rate of aversive experience (C). In response to these disruptions, the person will attempt to reduce their impact; the person's personal and environmental resources (G) will determine how successful these efforts will be. The inability to reverse the impact of an evolving event is hypothesized to lead to a heightened state of self-awareness (D), that is, a state in which attention is focused internally, which results in individuals becoming more aware of their thoughts, feelings, values, and standards. Increasing self-awareness has been shown to cause individuals to become

increasingly self-critical, to produce an increase in the discrepancy between ideal self and perceived self, and to produce dysphoria, which in turn is assumed to lead to some of the cognitive alterations, such as pessimism and attribution of failures to self, that have been emphasized by cognitive theorists. The model assumes that increasing self-awareness (D) and dysphoria (E) lead to many of the cognitive, behavioral, and emotional changes (F) that have been shown to be correlated with depression. These changes (F) are presumed to reduce the individual's ability to cope with the initial and subsequent depression-evoking events. For example, the dysphoria may further reduce the individual's social and other competence. The lack of competence in important spheres of functioning, in turn, may make it more likely that additional depression-evoking events (A) will occur. The proposed model allows for predisposing characteristics of various kinds (G) to either increase (vulnerabilities) or to decrease (immunities) the risks for depressive episode.

As indicated in Figure 1, predisposing characteristics are assumed to affect all elements of the model. A few illustrative examples: an individual with good coping skills would be more likely to be able to reverse the depressogenic cycle by implementing new behaviors to deal with the disruption (B) or by decreasing self-awareness by finding distractions and thereby staying focused on external events. The behavior of significant others in the person's environment may constitute a vulnerability to the extent that they selectively reinforce the depressed individual's symptoms and complaints.

The model allows for "feedback loops" that are seen as important for determining the level of severity and the duration of an episode of depression. Thus, becoming depressed (F) and thinking and behaving in the depressed mode would be expected to interfere with the individual's problem-solving skills (G) and consequently their ability to reverse the disruption (B) and the effects of the disruption (C). Feedback loops set the stage for a vicious cycle, but also for a benign cycle. By reversing any of the components of the model, the depression will be progressively and increasingly ameliorated.

LIBIDO

"Libido is a term used in the theory of the instincts for describing the dynamic manifestation of sexuality." Thus Freud began his 1923 encyclopedia article on the libido theory. He had used the term "libido" as early as 1894. His major theoretical treatise, *Three Essays on the Theory of Sexuality* (1905-1973, p. 255), placed libido at the center of his theories of development and psychopathology. In his *New Introductory Lectures on Psychoanalysis* (1933/1973, p. 95), Freud introduced his review and current synthesis of libido theory, noting that "the theory of instincts is so to say our mythology." Even in his later years libido remained a central construct in psychoanalytic theory, one side of the basic, pervasive, and instinctual dualism: sex and aggression, life and death. The metapsychology of libido's vicissitudes and reorganizations over the course of development through the psychosexual stages—oral, anal, phallic, latency, and genital—formed the core of early psychoanalytic theories of developmental psychology, psychopathology, and clinical practice.

Libido theory is among the most far-reaching and controversial notions in psychoanalysis. Now, as then, libido refers to the sexual biological instinct, drive, or psychic energy. However, whereas libido was not typically discussed in general physicians' offices in Freud's era, modern internists and specialty physicians recognize the importance of healthy sexual functioning as an important indicator of

overall health and quality of life. Thus, the term libido may also be used to refer to sexual instincts and sexual desire more generally.

Freud himself had strong allegiance and high hopes for biological causation and explanation, but still broadened his notion of libido to include the sensual as well as the more basic sexual aspects of life. Nonetheless, the relative emphasis upon biological versus social or psychological description still characterizes the ongoing controversy over libido theory. As early as 1916, Jung in his *Psychology of the Unconscious* attacked Freud's theory of libido, arguing that sexuality was only a variant of a more primal, undifferentiated form of psychic energy. In Jung's view, furthermore, sexuality emerged and predominated only in puberty, much later than in Freud's theory, with its focus on infancy and early childhood manifestations of libidinal expression and development. Rapaport replaced the libido concept with a more general, nonspecific drive energy as he cast traditional and id-oriented psychoanalysis into more general ego psychology. The growing concern with the bankruptcy of hydraulic, thermodynamic, and drive discharge models led to the elimination or de-emphasis of libido theory in many recent psychoanalytic reformulations. Klein, one of the most recent and influential systematizers of psychoanalysis, remarked that "in fact, the uncritical acceptance of libido theory with the newer current of ego psychology brings into sharp relief one of the focal dilemmas confronting psychoanalysis" (Klein, 1976, p. 147).

Aside from ongoing controversy over what role, if any, libido plays in psychoanalytic psychology, or with any other theory of behavior or pathology, two abiding domains or concepts derived from libido theory remain useful, especially when their metapsychological nature is appreciated and respected. One domain is the qualitative properties of libido (or any instinctual energy) which serve as structure, process, and organization for the so-called drive. Schafer notes that through variation in degree of anticathexis, cathexis, or hypercathexis of libido, we may posit dreams, symptoms, jokes, rituals, pathology, relationships, therapeutic effects, and so on—the concerns of psychoanalysis. He lists seven qualities of libido (Schafer, 1976, pp. 80–81):

1. Direction (sexual gratification),
2. Urgency or peremptoriness (unremitting pressure for discharge),
3. Mobility (readiness to divert itself into indirect channels when direct channels are blocked),
4. Dischargeability (its being reduced in quantity, hence in impetus, following certain activities),
5. Bindability (its being maintained in a fixed or blocked position by opposing energy),
6. Transformability (loss of its properties of direction, peremptoriness, probability), and
7. Dischargeability (a loss known as desexualization or deinstinctualization), fusibility (its capacity to blend with the energy of aggressive impulses/energy)

The second useful domain of concepts derived from libido theory are those of the developmental progressions of psychosexuality and object relations. In the theory of infantile sexuality, Freud described the maturation and successive reorganization of libido through the oral stage (birth to about 18 months), anal stage (18 to 36 months), phallic stage (three to five years), latency stage (middle childhood), and genital stage (adolescence and adulthood). Libidinal gratification was associated with sensuality or activity focused on each of the so-called erotogenic body zones implied in the stage sequence. Particular qualities of character and pathology were associated with the successes, failures, and compromises at each mutually influential step of the developmental process. A related progression of libido from autoerotism (gratification through one's own body) to narcissism (love of one's "self") and object love (gratification through investment and involvement with other people) complements the psychosexual progression, contributing yet another of the major developmental lines which form the framework for psychoanalytic diagnostic classification.

The scientific status of libido theory and its derived constructs remains to be established by empirical research, an effort abandoned by many in the belief that it is not researchable. Greater understanding will undoubtedly emerge with the coming of improved technology and conceptualization. Until then, libido theory remains an influential—though controversial—girder in the framework that guides a major portion of applied psychology: psychoanalysis.

LIE DETECTION

An instrument that monitors one or more involuntary physiological variables from a person under interrogation is popularly called a lie detector. The most common instrument for this purpose, the *polygraph,* normally monitors breathing movements, relative blood pressure, and electrodermal responses (which are related to the sweating of the palms). It is popularly believed that these or other instruments can identify lying by detecting some response or pattern of responses that is specific to deception, a “Pinocchio response” or pattern of reaction that everyone shows when lying but does not show when answering truthfully. No such specific lie response has ever been objectively demonstrated.

All one can determine from the polygraph chart is that the subject was relatively more disturbed or aroused by one question than by another; one cannot determine why the subject was aroused, whether the question elicited, for example, guilt or fear or anger. Moreover, polygraph responses that are indistinguishable from spontaneous ones can be elicited by biting one’s tongue or clenching the toes.

The examiner must therefore try to infer deception from the difference in reaction elicited by different types of questions. Since the 1950s, the standard question format has been the *control question test* or CQT. Relevant questions (e.g., “Did you take the $1000 from the safe?”) were intermixed with questions that refer in a general way to prior misdeeds of the subject. In the case of a theft investigation, for example, a control question might be, “Before last year, had you ever taken anything that didn’t belong to you?” The objective is to find two or three questions to which (in the opinion of the examiner) the subject’s answer is untruthful or, at least, about which the subject is uncertain that his answer is truthful. The theory of the control question test is that an innocent person, able to answer the relevant questions truthfully, will be more disturbed by these control questions and show stronger physiological reactions to them, whereas the guilty person will react most strongly to the relevant questions.

In the *directed lie test,* or DLT, the subject is required to deny such common sins as “Have you ever committed any sort of traffic violation?” The DLT assumes that subjects who answer the relevant questions truthfully will be relatively more disturbed by these directed-lie questions than by questions about the crime of which they are suspected. Most polygraph testing of job applicants or employees in federal security agencies now relies upon the DLT.

A different method of polygraphic interrogation, the *guilty knowledge test* or GKT, attempts to determine whether the suspect recognizes facts or images about the crime that would be known only to someone who had been present at the scene. The GKT consists of a series of multiple-choice questions such as: “The killer wore a ski mask. If you are the killer, you will know the color of the mask. Was it: Brown? Blue? Red? Black? Yellow? Green?” In the GKT, the subject’s physiological responses to the incorrect alternatives serve as genuine controls. If he responds differentially to the correct alternatives, then guilty knowledge can be inferred. The GKT is used extensively by police investigators in Israel and in Japan but seldom in the United States.

The lie detector test is very effective in inducing confessions or damaging admissions, at least from unsophisticated suspects. In perhaps 14 states, polygraph evidence is admissible in criminal trials when both sides have so stipulated prior to testing. This normally happens when the prosecution’s case is so weak that they offer to drop the charges if the defendant passes the lie detector. The defendant must stipulate, however, that the test results can be used in court against him should he or she fail the test. In its 1993 *Daubert* decision, the Supreme Court ruled that federal judges must at least hold evidentiary hearings whenever lie detector (or other allegedly scientific evidence) is proffered. Such hearings to date have almost invariably led to the exclusion of polygraph test results. In its 1998 *Scheffer* decision, the Supreme Court ruled that the per se exclusion of polygraph evidence does not violate the defendant’s Sixth Amendment right to present a defense.

Accuracy of Lie Detection. Polygraph examiners claim very high rates of accuracy, ranging typically from 95% to 99%, but these claims have not been supported by credible research. Because one cannot simulate in the laboratory the emotional concerns of criminal suspects being interrogated in real life, studies of lie detector validity must be done in the field situation. Interrogation of criminal suspects who have failed polygraph tests produces confessions in perhaps 20% of cases, thus verifying the test that produced the confession. Such confessions sometimes clear other suspects in the same case. To determine the accuracy of diagnoses based just on the polygraph recordings, the charts from such verified tests are then scored by a different examiner than the one who administered the test.

But suspects who fail the polygraph and then confess may not generally be representative of guilty suspects. Moreover, because testing of multiple suspects normally ceases after one suspect has been diagnosed as deceptive, suspects verified as innocent by another’s confession will usually have been tested prior to the suspect who confessed and their charts scored as truthful. Therefore, field studies based on charts verified by polygraph-induced confessions necessarily overestimate the validity of the polygraph because they exclude charts from guilty suspects who passed the test and also charts from innocent suspects who failed the test. By 1998, four such studies of polygraph accuracy had been published in scientific journals. Where chance accuracy would lead to 50% correct classification, in the four mentioned studies the charts of the innocent suspects were scored as “deceptive” in 39.5% of the cases, indicating that the lie detector tests are strongly biased against the truthful person. The accuracy of the GKT has not yet been adequately studied in real life applications. Laboratory stud-

ies agree, however, in showing that the GKT is highly accurate in identifying innocent suspects and, with six or more questions, in identifying guilty suspects as well.

LIFE-SPAN DEVELOPMENT

The point where change occurs throughout the life cycle is critical. Traditional approaches to human development have emphasized change from birth to adolescence, stability in adulthood, and decline in old age. Sears and Feldman have captured the flavor of some of the most important adult changes. The changes in body, personality, and abilities may be great during these later decades. Strong developmental tasks are imposed by marriage and parenthood, by the waxing and waning of physical prowess and of some intellectual capacities, by the children's exit from the nest, by the achievement of an occupational plateau, and by retirement and the prospect of death.

A number of stage-crisis theories have been developed to explain the change adults undergo, the best known being Erikson's theory and, in the popular literature, Gail Sheehy's *Passages.* Many theorists and researchers, however, have not been satisfied with the stage-crisis approaches to adult development. To obtain a more accurate view of adult development, many experts believe that the study of life events adds valuable information. Hultsch and Deutsch point out that our lives are punctuated by transitions defined by various events. Particular emphasis is placed on the stressful nature of these events. Events typically thought of as positive (marriage or being promoted at work), as well as events usually perceived as negative (death of spouse, being fired from work), are potentially stressful. Factors that can mediate such stressful life events include internal resources (physical health, intellectual abilities) and external resources (income, social supports). Adaptation involves the use of coping strategies that result in behavioral change.

Broadly speaking, there are two theoretical approaches to the study of personality development, one focusing on similarities and the other on differences. The stage theories all attempt to describe the universals—not the individual variation—in development. Farrell and Rosenberg suggest a more complex model, one anchored in the idea that individuals are active agents in interpreting, shaping, and altering their own reality.

In a recent discussion of life stress, I. G. Sarason has called attention to the wide array of individual differences in the frequency and preoccupying characteristics of stress-related cognitions. Although the most adaptive response to stress is a task orientation that directs a person's attention to the task at hand rather than to emotional reactions, some individuals are task-oriented while others are not.

Sarason emphasizes that the ability to set aside unproductive worries and preoccupations is crucial to functioning under stress. At least five factors influence how an individual will respond to life stress, according to Sarason:

1. The nature of the task or stress
2. The skills available to perform the task or handle the stress
3. Personality characteristics
4. Social supports available to the person experiencing stress
5. The person's history of stress-arousing experiences and events

But while adults are likely to experience one or more highly stressful events during their lives, an increasing number of individuals are reaching late adulthood in a healthier manner than in the past.

LIMBIC SYSTEM

Broca described the "great limbic lobe" of the brain as a large cerebral convolution that lies medially and envelops the brain stem and is common to all mammals (Broca, 1878). The limbic lobe was thought to be important in olfaction due to its dense connections with the olfactory cortex, and was often referred to as the *rhinencephalon* (smell brain). Papez, in 1937, proposed that the rhinencephalon was also important in emotional behavior. In 1952, MacLean coined the term *limbic system* to refer both to a medial part of the

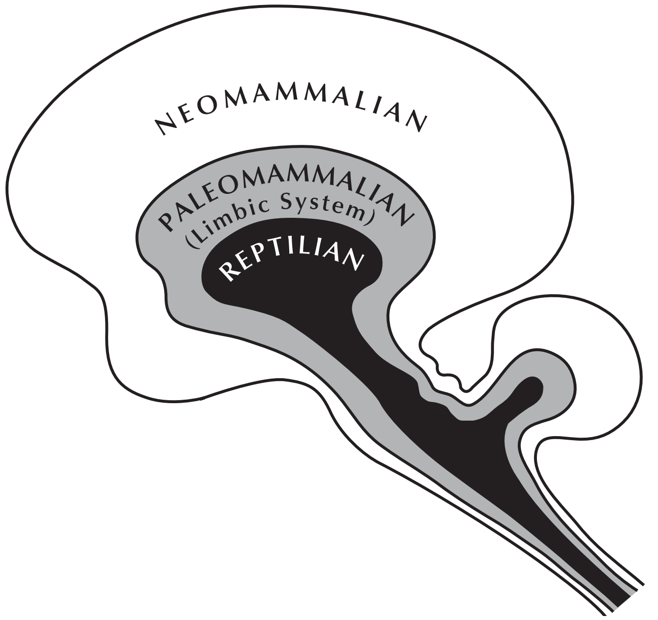

Figure 1. Limbic system of the brain in relation to neomammalian and reptilian structures.

cortex that enveloped the brain stem and to subcortical structures that were tightly associated with this region. He based this grouping not only on its anatomic location but also on evidence that this region was well developed only in mammals, was phylogenetically older than the more peripheral neocortex, and appeared to be important in emotional and social behavior (1990). The limbic, or paleomammalian, system of the brain is shown in Figure 1 in relation to higher cortical (or neomammalian) and deeper brain (or reptilian) structures. MacLean's subdivisions of the limbic system (1990) include the amygdalar, septal, and thalamocingulate divisions shown in Figure 2. Extensive preclinical and clinical observations have suggested that the limbic system is critical in learning, memory, emotions, social behaviors, and autonomic responses. This essay will briefly review the definition and anatomy of the limbic system, describe the three limbic subdivisions, and discuss evidence for and against the limbic system construct.

Definition and Anatomy

Although there is no clear consensus, the following regions are generally considered part of the limbic system: The cortical structures include the cingulate gyrus, subcallosal gyrus, hippocampus, and olfactory cortex. Subcortical regions include the amygdala, septum, pellucidum, epithalamus (habenula), anterior thalamic nuclei, hypothalamus, and parts of the basal ganglia. In addition, several closely linked cortical structures that appear important in emotional behavior are also considered part of this circuit and are often referred to as paralimbic. These regions include the anterior temporal polar cortex, medial-posterior orbitofrontal cortex, and insular cortex (Mesulam & Mufson, 1982).

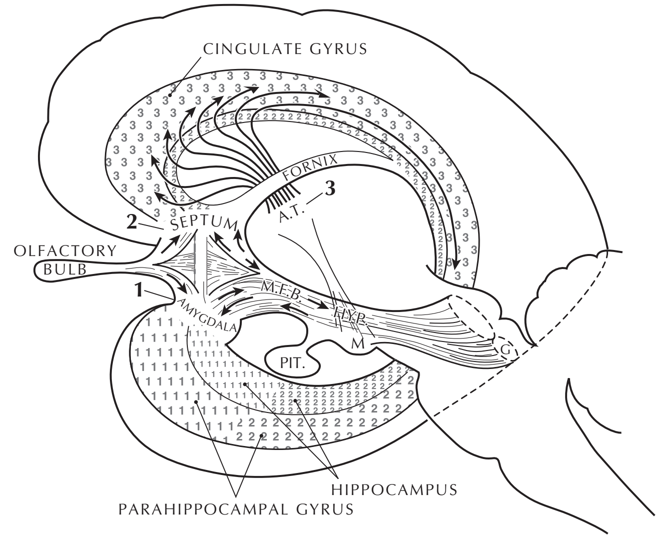

Figure 2. Maclean's subdivisions of the limbic system.

Maclean's Proposed Limbic Subdivisions

Amygdalar Division

MacLean (1990) emphasizes that this region is involved in self-preservation behaviors such as those required in the search for food, including fighting and self-defense. Stimulation of this area in humans may produce fear and anxiety.

Septal Division

The septal region may subserve behaviors related to sexual function and procreation. MacLean (1990) emphasizes that septal stimulation in humans can produce pleasurable sensations and in animals can elicit social grooming as well as genital tumescence.

Thalamocingulate Division

This region represents the phylogenetically newest subdivision of the limbic system. It is present in mammals but not in reptiles. Several typical mammalian social behaviors are associated with this area, including extensive mother–infant bonding, infant crying, and play. Lesions of this region in nonhuman mammals often produce social apathy; even mothers will neglect their young (MacLean, 1990).

In addition to these social functions, the cingulate, particularly its anterior extent, is believed to be important in selective attention and pain (MacLean, 1990).

Evidence for and Against the Limbic System Construct

Extensive research suggests that limbic structures are important in emotional behavior. What is uncertain is the extent to which limbic regions and associated brain structures alone are critical in emotional regulation and whether

the limbic system functions as a unified network. Much of the clinical evidence for the unified network concept has come from studies of psychomotor seizures (Jasper, 1964), although recent functional imaging studies in humans also support the notion of a limbic system concept (George et al., 1995). Critics of the limbic system construct (Kotter & Meyer, 1992; LeDoux, 1996) point out that no two authorities can agree on which structures should be included in the limbic system. Also, limbic structures are connected with virtually all areas of the brain, so critics argue that one should then consider the whole brain the limbic system. Moreover, if the limbic system is defined functionally as that part of the brain involved in emotion, evidence suggests that the neocortex may be important in the regulation and recognition of emotions and that limbic regions such as the hippocampus and cingulate are important in functions other than emotion, such as memory, cognition, and selective attention.

Conclusions

Extensive preclinical and clinical observations have suggested that the limbic system structures are critical in emotional behavior. Limbic structures have also been found to be important in social behavior, cognition, and autonomic responses. The limbic system, however, has extensive direct interconnections with all brain regions, and the extent to which the limbic system functions as a network itself remains to be determined. Perhaps the limbic system concept will lose its heuristic appeal as we improve our definitions of emotional states, and the roles of discrete structures and small circuits important in motivation (Kalivas, Churchill, & Romanides, 1999), fear (LeDoux, 1996), and other emotional behaviors. Alternatively, as some imaging studies suggest, we may actually confirm that emotional behaviors do not arise from the activity of single brain regions, but instead emerge from the coordinated action of many connected structures. New techniques in functional imaging and noninvasive regional brain stimulation will allow for direct testing of the limbic system construct in normal function and in psychiatric and medical disorders. Broca's limbic lobe, initially thought to be important by some only in olfaction, is certainly no longer ignored.

LITERATURE AND PSYCHOLOGY

The emergence of psychology as a separate discipline in the late nineteenth century brought to the forefront the relation of this new science to the humanities. Two great figures of that time, William James and Sigmund Freud, loomed large in this issue. Both were trained in medicine and psychology, but viewed themselves as psychologists; both were attracted to philosophy; and both were to receive renown as writers. William James's duality was mirrored in his younger brother Henry, whose reputation as a writer is based importantly on his psychological insights and understanding.

It is fitting that Freud should have met William James in 1909 on his only visit to America. As he evolved psychoanalysis, he always understood that humanistic studies were vital to his thinking, and he criticized the lack of such studies in the medical curriculum, especially for the training of someone who was to become a psychoanalyst. The cornerstone of his clinical theory was the Oedipus complex, influenced not only by his clinical observations and his self-analysis, but also by his familiarity with Sophocles' tragedy, which he had translated as a youth. The specific writers who influenced him were many, including Shakespeare, whose works he had read in English as a youth; Goethe, whom he was fond of quoting; and Dostoyevski, whose psychological acumen he so admired. Freud created not just a

theory of the human mind, but works of great literary merit. He wrote psychology as literature on a level that has not been equaled since.

Humans are linguistic beasts, and Freud recognized that any comprehensive theory of human behavior must come to grips with this simple fact. Freud used the analysis of language as the foundation on which he erected his theoretical edifice. Freud's analysis of dreaming provided him with his basic concepts concerning the operation of the human mind and its cognitive processes. Concepts with linguistic referents inform his analysis of dreamwork, including censorship, condensation, displacement, secondary revision, and symbolization.

The importance Freud gave to language is reflected in all areas of his thought. He began with an analysis of slips of the tongue and other verbal parapraxes. Similarly, he elaborated how wit and joking are forms of language that reveal the complex workings of the mind. Moreover, Freud evolved a "talking cure," the technique of psychoanalytic therapy in which two people converse as a means of alleviating neurotic suffering.

The concern with transformational processes provides a fundamental meeting ground for psychology and literature. We interpret literature and we interpret dreams, and in this way recognize that hermeneutics, the study of the interpretive process, is central to psychology and literature. Freud was preoccupied with these transformational processes in his theory not only in cognition—as in the distinctions of unconscious versus conscious, primary process versus secondary process, repressed versus return of the repressed, and manifest dream versus latent dream—but also in transformation or vicissitudes of instincts, as in love versus hate.

This transformational or two-language nature of psychoanalysis brings it into congruence with a number of contemporary approaches to language, including the structuralist approach of the French psychoanalyst Jacques Lacan and the deconstructionist approach of Jacques Derrida. However, it is in the transformational-generative theory of language that we find striking similarities to the nature of Freud's thought. The parallel between Freud and Chomsky has been amplified by M. Edelson, who notes that both men posit the presence of deeper structures forming the basis of surface structures, as well as stress the importance of transformational operations by which the language of the deep structure is represented in the language of the surface structure. Echoing Freud's basic distinction between primary process thought and secondary process thought, Fodor assumes a private language that is the precursor of the public language. In consonance with Chomsky's idea of "language and unconscious knowledge," he holds that to learn a language we must have available another private language. Fodor is led to speculate on the "vocabulary" of the code by which the private language is transformed into the public language.

Literature of the late nineteenth and early twentieth centuries, as in the works of Proust and Joyce, exemplifies the concern with levels of language. Joyce's novels can be considered as progressive movements from the public language of the conscious to a predominant emphasis on the private language of the unconscious. It is as if Joyce wished to write in the private language that forms the substrate of all literary works. It is poetry, however, that reveals most directly the transformation process from the private to the public language. The poet's language bridges primary and secondary processes and focuses on the transition from one to the other. Early in this century F. C. Prescott recognized the parallel between such poetic tropes and the process of dreamwork developed by Freud, a parallel subsequently elaborated by the psychoanalyst E. F. Sharpe. Thus, psychoanalysis, literature, and linguistics converge upon transformational operations, and the problem of interpretation of the text, or hermeneutics, becomes a central issue.

Because psychoanalytic interpretations of literature initially emphasized the major developmental themes explicated by Freud, there has been continuing interest in the oral, anal, and phallic aspects of literature, often with predominant emphasis on the Oedipal state of development. With the development of ego psychology within psychoanalysis, psychoanalytic literary criticism took a turn toward emphasizing the more adaptive, synthesizing aspects of literary productivity. The emphasis of ego psychology was to construe literary effort as positive, coping behavior in which the regression was purposive and controlled, otherwise the fantasy emanating from the primary process would become too private and preclude artistic communication with the reader. Erikson's work gave psychoanalytic interpretations of literature a firmer foothold by emphasizing the cohesive, integrative role of the writer's ego identity on the one hand, and his or her place within the context of the social, cultural, and historical forces on the other hand.

Freud turned more to pre-Oedipal issues late in his life, as he distinguished between the psychological development of the male and female child, and recent feminist literary criticism has moved in this direction. Freud maintained that the pre-Oedipal relationship with the mother was of more basic significance for the development of the female child than was the Oedipal period. Such a formulation is central in the feminist approach to problems of female identity formation. The intense interest feminist critics are displaying in this issue of female identity formation in relation to writing is one example of the mutual contribution of literature and psychology in the development of both.

Using a paradigm centering on Oedipal issues, the literary critic Harold Bloom has made bold forays into psychoanalytic concepts in advancing a theory of literature. Bloom emphasizes rhetorical tropes in poetry as manifestations of mechanisms of defense. More generally, Bloom is concerned with the thesis that repression as a defense operates importantly in how writers deal with their literary precursors. Repression operates by causing writers to mis-

read their important precursors, and by otherwise distorting their influence.

Because Bloom's thesis implies that all reading of prior texts is a misreading of these texts, it broaches the important problem of the psychological bases of the reader's response to literature. The foremost theoretician of this issue has been N. N. Holland. It is apparent that every reader of a text responds to the text with some interpretive schema that reflects her or his personality.

Another promising approach is to consider different analyses of the same text by a group of literary critics, in an effort to identify common interpretational structures irrespective of each critic's idiosyncratic interpretation of the text. Such meta-analyses of interpretations of literature bear important similarities to the need in clinical psychology to identify common elements and structures in the interpretive diagnostic and psychotherapeutic efforts of clinicians.

The structuralist view rejects the idea that texts exist to be interpreted, or that they contain truth or meaning. Structuralists seek a systematic "scientific" framework that allows them to reduce texts to basic semiotic categories, such that the experience of the reader is nullified. The text reads itself.

Lacan, influenced by the structural linguistics of Saussure and the structural anthropology of Levi-Strauss, has as a central tenet the idea that the unconscious is structured like a language. Lacan rejects American psychoanalytic ego psychology and its emphasis on the adaptive, synthesizing, and integrative aspects of the ego in literary creativity. In contrast, Lacan stresses the alienated otherness of the ego and self, which he considered central to Freud's concepts of narcissism and identification. The infant first begins to develop its alienated self in what Lacan calls the "mirror stage" of development, such that the mother as a mirror is the basis of the infant's self as the other. Lacan's idea of the mirror stage allows the reintroduction of the concept of *imago* into literary analysis and provides a link between psychoanalytic conceptions and the archetype of Jung.

The deconstructionist program has been strongly influenced by Heidegger, Freud, and Lacan. More severely than Lacan, Derrida wishes to establish the text as both a presence and an absence, such that the text is ultimately effaced. The text of Freud or any writer is erased, deconstructed, or dismantled in order that it can be reconstructed or rewritten so as to show the text what it "does not know." The ultimate effect of Derrida's criticism is to render texts, Freudian or otherwise, open-ended, without closure, never fully fathomed, never fully constructed, or deconstructed. As in Freud's final commentary on psychoanalytic therapy, the text becomes both terminable and interminable.

What might the psychologist learn from literature? Perhaps the most psychologically astute of these poets was William Blake, whose startlingly acute and direct penetrations of the human psyche have yet to be adequately recognized and studied. Not only were his ideas precursors of both Freud and Jung, but the entire corpus of his work, both literary and artistic, also demands an exegesis in its own psychological terms that could yield important conceptualizations of the human personality.

The Romantic turn toward the self is strongly exemplified in Wordsworth, whose poetic texts contain some of the most vivid recapitulations of early childhood experience, including infancy. The complex ideas of Coleridge speak to many contemporary psychological issues, including his concepts concerning imagination and fantasy. The contributions of Keats to psychological understanding have been more generally recognized, including his emphasis on identity as a crucial element in personality formation and his ideas about the creative process, including *negative capability,* his oxymoron for a process reaching into issues central to Freud's theory of dreams.

Psychology, in seeking a systematic understanding of the human personality, needs to be reminded by literature where its conceptions fall short of the depth, complexity, and richness that characterize the human being.

J. Bieri

LOGICAL POSITIVISM

Logical positivism is an approach to philosophy of science that was developed by philosophers in the 1920s and 1930s in Vienna and Berlin (for review see Suppe, 1974). These philosophers pursued a common goal: to rid philosophy of the excesses of metaphysical idealism by clarifying philosophical language. This project called for strict logical and empirical criteria for assigning meaning to terms and truth value to propositions. The logical criteria were those of deductive logic, and the empirical criteria were appropriated from a misreading of Wittgenstein. Members of the Vienna Circle mistook Wittgenstein's quite imprecise claims about "atomic facts" as implying that science contained a language of facts independent from theoretical assumptions. Bloor (1983) has provided a corrective reading of Wittgenstein.

These philosophers wanted to set philosophy straight by making it conform to deductive logic and the meaning criteria of naive empiricist epistemology. In order to correct philosophy and set it on "the sure path of science," the positivist movement concluded that it was necessary to *justify* scientific practice philosophically. The primary concern of philosophy of science was the context of justification, where one could show via a reconstruction of history that scientists' products (i.e. their theories) changed and developed in a pattern consistent with logical reasoning. From this perspective, science is the set of theoretical and empirical propositions devised by physicists, chemists, and biologists

to describe and explain the world. Science differs from nonscience by adhering both to logical truth and to empirical truth.

Overall, the logical positivists were not enthusiastic about psychology. Attempts to base the authority of deductive logic on “natural” habits of mind or psychological processes were rejected as psychologism. In order for the truths of logic and mathematics to command the high philosophical status of clear and certain (also transhistorical and universal) truth, it was necessary that these truths be objectively true. By definition, objective truth meant truth independent of subjective experience. Consequently, any attempt to base the truths of logic and mathematics on a study of cognitive contents and/or processes undermined their privileged status and authority.

Epistemologically speaking, the positivist program assumed that the relationship between human perception and the world was uncomplicated, with “basic facts” being “given” in direct observation. Psychologically speaking, the scientist or at least the collective community of scientists was conceived as a perfect information processing device capable of isomorphic inputs and outputs. Moreover, the claim was made that the language of science could be neatly bifurcated into distinct and nonoverlapping sets: (1) basic statements about the world or the language of direct observation (e.g., blue, hard, hot), and (2) theoretical terms (e.g., wavelength, density, kinetic energy) which, when introduced, had to be linked to observation terms via various explicit correspondence rules (i.e., operational definition).

The project of logical reconstruction consisted of demonstrating how new scientific knowledge was achieved through the accumulation of more extensive and accurate observations coupled with rigorous application of deductive logic. Scientific theories were reconstructed as if they were axiomatic systems like the postulates of pure geometry, their only difference being that they also had empirical content. In the later form known as “logical empiricism,” the historical picture that emerged was a reconstruction of scientific development in which both rationality, as adherence to deductive logic, and progress, as movement toward ever more comprehensive theories, were inevitable (Feigl, 1970; Hempel, 1965; Nagel, 1961).

The logical positivists and logical empiricists accomplished their reconstruction of science by ignoring many of the particulars of what individual scientists might have done and said. Science as described by the logical positivists and logical empiricists was an abstraction, a set of propositions often taken out of historical context and only loosely tied to people called scientists.

Whether or not scientists actually behaved in the manner described by this reconstruction was deemed irrelevant to the paramount task of establishing that science in the abstract somehow proceeded along logical lines and therefore made valid claims to “Truth.” Thus, by focusing on an abstraction called “science,” the project of logical reconstruction could be carried forward without entertaining the sort of evidence that might be provided by detailed sociological and psychological studies of scientists’ actual practices. As subsequent work in the history of science showed, it is a bitter irony that the philosophical movement that promised to rid philosophy of speculative idealism only reinstated a kind of idealism in the logical reconstruction of science without scientists.

Much of psychology itself was judged by the logical positivists to be defective and in need of the purification they offered (Bergmann, 1940; Carnap, 1932/1959; Feigl, 1945). To complicate matters further, the positivist prescriptions for doing philosophy were widely taken as prescriptions for doing science. This was evident in the often tacit but nevertheless dogmatic adoption of major tenets of positivist philosophy by empirically oriented psychologists (for review see Koch, 1959–1963), who apparently overlooked the antidogmatic stance of most members of the Vienna Circle. Smith’s (1986) study of leading behaviorists in the 1930s and 1940s raises doubts about the direct connection between their views and those of the logical positivists, but he also noted that by the 1950s logical empiricism was widely accepted as the standard account of science among psychologists in general. Although some of the logical positivists and logical empiricists advocated types of behaviorism at times, Smith has shown that it is clearly incorrect to call Skinner a logical positivist.

LOGOTHERAPY

The Greek word *logos* denotes meaning, and logotherapy can be defined as a meaning-centered psychotherapy. It was founded by Viktor E. Frankl. The motivational theory underlying Frankl's approach focuses on what he calls "the will to meaning," in counterdistinction to "the will to power" and the "will to pleasure" (the pleasure principle). Today more and more patients complain of a feeling of meaninglessness, and many of the ills and ailments of our time, according to Frankl, can be traced back to this frustration in a "search for meaning." The result of this state of affairs is the neurotic triad: depression, aggression, and addiction. Empirical evidence has been furnished by logotherapists that the feeling of meaninglessness is at the root of the neurotic triad.

No logotherapist can hand out or "prescribe" meanings. It is the objective of logotherapy to *describe* the process of meaning perception by way of a phenomenological analysis, so as to find out how normal people arrive at meaning and consequently at a sense of fulfillment.

From such analysis Frankl has distilled his "logo theory," according to which meaning can be found in doing a deed, creating a work, or experiencing something (art, nature, culture, etc.). Logotherapy also offers a special technique for the treatment of obsessive–compulsive and phobic neuroses. This technique is called *paradoxical intention* and can be defined as having the patient try to do, or wish to have happen, precisely that which he or she fears. The effect is to disarm the anticipatory anxiety that accounts for many of the feedback mechanisms that initiate and perpetuate the neurotic condition. Another logotherapeutic technique, called *dereflection,* is designed to counteract sexual neuroses such as frigidity and impotence.

LONGITUDINAL STUDIES

Longitudinal studies represent a research design wherein individuals or groups are observed or repeatedly assessed over a considerable period of time in order to assess change. The longitudinal study is an important research method in developmental psychology, where time-related phenomena are under investigation. Often the intent is to study behavioral or physiological changes that may occur in subjects as they grow older. Two major approaches have been employed to investigate the time-related trajectory of change: cross-sectional and longitudinal designs. *Cross-sectional* studies measure a given dependent variable (e.g., IQ) in several different age cohorts. In this type of study one might measure IQ in groups that were, for instance, 4, 7, 10, and 12 years old. *Longitudinal* investigations repeatedly assess the dependent variable for the same cohort of subjects over time (e.g., when they are 4, 7, 10, and 12 years of age). Technically, a longitudinal study is any investigation in which repeated measurements are recorded on the same subjects over time. However, the term "longitudinal" is typically not used for studies in which the time span is less than several months or years.

Longitudinal studies have a long history in various specialties of psychology as well as many other fields, ranging from health to sociometric status. The late nineteenth century is generally cited as the time when psychology began to seriously employ longitudinal research. However, the classic study of infants by D. Tiedemann, entitled *Beobachtungen über die Entwicklung der Seelenfähigkeit bei Kindern,* was published in 1787. Early work using longitudinal studies significantly influenced the nature of developmental psychology.

One major strength of longitudinal designs is that researchers are able to follow the same subjects over the period of the study. This permits examination of change in the same individuals as they develop or decline. Consequently, longitudinal investigations permit more direct inferences regarding development than cross-sectional studies. Longitudinal studies with multiple measures such as the examples noted above (i.e., assessments at ages 4, 7, 10, and 12) are also preferred because of strong statistical power in determining the trajectory of a change over time.

Longitudinal designs also present certain methodological difficulties. Since the subjects are measured repeatedly, it is possible that changes may be observed which are partially due to the effects of repeated assessment reliability and the continuing attention or Hawthorne effect over time. Another potential problem is subject attrition: since longitudinal studies often continue for an extended period of time, a certain number of subjects may be lost for a variety of reasons (death, moving, refusal to continue). As with most experimental designs, most problems associated with longitudinal studies can be successfully circumvented by ingenious researchers. Such studies remain an important research strategy in psychology, although they are not frequently undertaken because of the time and expense involved.

LONG-TERM POTENTIATION

Virtually all notions about memory hold dear the central notion that learning relies on the modification of synaptic function. In recent years considerable attention has focused on one particular form of use-dependent synaptic plasticity known as long-term potentiation (LTP). LTP was first discovered by Terje Lomo, who observed that repetitive high frequency electrical stimulations of the pathway from the cortex to the hippocampus resulted in a steeper rise time of the excitatory synaptic potential as well as recruitment of spike activity from a greater number of cells. Moreover, these changes in synaptic and cellular responses to subsequent single shocks lasted several hours, suggesting the possibility of a lasting memory mechanism.

Two key properties of LTP are most notable: First, LTP is *specific* to those synapses activated during stimulation. Other neighboring synapses, even on the same neurons, are not altered. This phenomenon parallels the natural specificity of our memories, and would be a key requirement of any useful cellular memory mechanism. The property of specificity may be key to the storage capacity of brain structures because each cell can participate in the representation of multiple memories composed from distinct subsets of its synaptic inputs.

Second, LTP is *associative* in that potentiation characteristically occurs across multiple inputs that are stimulated simultaneously. The property of associativity is consistent with Hebb's (1949) postulate that increasing synaptic efficacy requires the repeated activation of a presynaptic element AND its participation in the success in firing the postsynaptic cell, as indeed occurs in associative LTP when several inputs are simultaneously active.

Considerable evidence has now accumulated revealing the cellular and molecular mechanisms that mediate the properties of different forms of LTP, as well as the cousin synaptic plasticity mechanism called long-term depression, in both the hippocampus and the neocortex (Bear, 1996; Bliss & Collingridge, 1993; Madison, Malenka, & Nicoll, 1991; Malenka, 1994).

LTP and Memory: Is There a Connection?

As Stevens (1996) once put it, the mechanism of LTP is so attractive that it would be a shame if LTP turned out not to be a memory device. But there should be no doubt about the fact that LTP is not memory; it is a laboratory phenomenon never observed in nature. The best we can hope for is that LTP and memory share some of their physiological and molecular bases. In recent years evidence from two general strategies have emerged to provide supporting connections between LTP and memory.

Behavioral LTP. One strategy is to determine whether learning produces changes in synaptic physiology similar to the increases in synaptic and cellular responses that occur after LTP. Recently, Rogan, Staubli, & LeDoux, (1997) offered the most compelling evidence to date that these aspects of LTP are a consequence of natural learning. In this case the circuit under study was the pathway from the medial geniculate nucleus of the thalamus to the lateral amygdala nucleus that is part of the critical circuit for auditory fear conditioning. These investigators found that repeated pairings of auditory stimuli and foot shocks train rats to fear the tones. Furthermore, this learning experience alters evoked sensory responses to the tones in the same way as LTP in that pathway. Thus, in rats with properly timed tone–shock pairings, tones produce evoked potentials of greater slope and amplitude, just as do electrical stimulus trains applied to this pathway. No enhancement of field potentials was observed with unpaired tone and foot shock presentations, even though this conditioning control leads to as much of a behavioral response (freezing) as paired presentations because even the unpaired control rats learn to freeze to the environmental context where shocks are received. Furthermore, this behavioral LTP is enduring, lasting at least a few days, as long as the behavioral response during extinction trials. Other studies have shown a similar pattern of enhanced strength of connections among neurons in the motor cortex of rats trained on a skilled reaching task (Rioult-Pedotti, Friedman, Hess, & Donoghue, 1998).

Blocking LTP and memory. Perhaps the most compelling and straightforward data on a potential connection between the molecular basis of LTP and memory has come from experiments in which a drug is used to block LTP and, correspondingly, prevent learning. These studies were based on the observations that induction of the most prominent form of hippocampal LTP is dependent on a specific glutamate receptor known as the N-methyl-D-aspartate (NMDA) receptor, and that drugs such as D-2-amino-5-phosphonovalerate (AP5) selectively block the NMDA receptor and prevent hippocampal LTP while sparing normal synaptic transmission. Thus, to the extent that the role of the NMDA receptor is fully selective to plasticity, one might predict these drugs would indeed block new learning without affecting nonlearning performance or retention of learning normally accomplished prior to drug treatment.

Consistent with these predictions, some of the strongest evidence supporting a connection between LTP and memory has come from demonstrations that drug-induced blockade of hippocampal NMDA-receptors prevents hippocampal-dependent spatial learning (Morris, Anderson, Lynch, &

Baudry, 1986). Additional experiments revealed no effect of AP5 on retention of the same spatial learning when training was accomplished prior to drug treatment. This would be fully predicted because NMDA receptors are viewed as required only for the induction of LTP and not for its maintenance. In addition, targeted genetic manipulations have now shown that knocking out NMDA receptors (McHugh, Blum, Tsien, Tonegawa, & Wilson, 1997) or later stages in the cascade of molecular triggers for maintenance of LTP (e.g., Silva, Paylor, Wehner, & Tonegawa, 1992) also results in severe memory impairments. These studies have also shown some restrictions on the role of NMDA-receptor mediated LTP in spatial memory. Recent experiments have indicated that blocking NMDA-dependent LTP does not necessarily prevent the encoding of a new spatial environment (Bannerman, Good, Butcher, Ramsay, & Morris, 1995). However, NMDA-dependent LTP may be necessary to remembering new episodes within a familiar space (Steele & Morris, 1999).

LOOSE ASSOCIATIONS

The most important source of data for assessing patients with psychiatric disorders is speech behavior during a clinical interview. One critical component of this assessment is the patient's ability to produce coherent conversational discourse.

The sine qua non of disrupted discourse coherence consists of loose associations. A synonymous term currently used is "derailment." Loose associations or derailments are suspected when the listener has significant difficulty following or tracking continuous, conversational speech. The overall intention or focus of the utterance is obscure, and the speaker seems to shift idiosyncratically from one frame of reference to another (Andreasen, 1979a). A typical case of loose associations is illustrated in the following:

Interviewer: Tell me about where you live.
Patient: I live in one place and then another place. They're black and white you know. That's why I love Christmas and stuff because, you know, it's different colors. I used to live in Brooklyn. (Hoffman, Kirstein, Stopek, & Ciccheti, 1982)

Here the patient seems to respond to the interviewer's prompt but then abruptly switches to a Christmas motif that fails to elaborate on the "where I live" theme and does not, in itself, make a point. Of note is that each of the sentences, when considered separately, is quite ordinary and grammatical. Deviance reflects the juxtaposition of phrases and sentences.

A more complex form of loose associations is illustrated by the following (Hoffman, 1986):

Interviewer: Did you ever try to hurt yourself?
Patient: I cut myself once when I was in the kitchen trying to please David. I was scared for life because if David didn't want me then no man would.

Here the patient seems to be talking about two frames of reference, the first pertaining to cutting herself, presumably while preparing food, and the second pertaining to reasons for being suicidal. Shifts between the two frames of

reference are expressed without warning to the listener. In other words, the patient did not state, "I never intentionally hurt myself but I was so upset about David that . . ." These shifts of frame ordinarily help the listener to make the transition from one frame of reference to another (Hoffman et al., 1982).

Most typically, loose associations are produced by patients with schizophrenia. However, some patients with aphasia or brain disturbances secondary to drug intoxication or organic encephalopathy may also produce such language disturbances. A related language difficulty is referred to as "flight of ideas," and is typically associated with patients with mania or amphetamine-induced states. Some researchers have not distinguished flight of ideas from loose associations (Andreasen, 1979a), but there is some empirical evidence that the two terms refer to distinct phenomena (Hoffman, Stopek, & Andreasen, 1986). In the case of flight of ideas, conversational speech yields unannounced and disruptive shifts in frame of reference, but is also accompanied by rapid production of speech. Most importantly, the speaker in the former case seems to retain the ability to flesh out particular themes or topics within a particular frame of reference. In contrast, looseness of associations suggests a sustained inability to fully and coherently elaborate on any theme or topic. Although the presence of these language difficulties favors some psychiatric diagnoses over others, they, in themselves, are not diagnostic of a specific disorder. For instance, it has been well established that some apparently normal speakers occasionally produce loose associations (Andreasen, 1979b; Hoffman et al., 1986).

There is some research exploring the cognitive and/or neurobiological basis of loose associations. Some recent studies have suggested that alterations in semantic processing produce loose associations and related language disturbances in patients with schizophrenia (Goldberg et al., 1998; Spitzer, 1997). Another recent study of regional cerebral blood flow using positron emission tomography suggested that these language difficulties arise from an imbalance of regional cerebral activation, with reduced activation in inferior frontal and cingulate brain regions combined with excessive activation in hippocampal regions (McGuire et al., 1998). Additional research on the neurocognitive basis of loose associations is needed.

LOVE

What Is Love?

In romantic relationships, psychologists distinguish between *passionate* love and *companionate* love. Passionate love is defined as an intense longing for union with the other. It is associated with a confusion of feelings: tenderness and sexuality, elation and pain, anxiety and relief, altruism and jealousy (see Hatfield & Rapson, 1993, 1995 for a review of this research). Companionate love, a less intense emotion, is characterized by affection, intimacy, attachment, and a concern for the welfare of the other (see Sternberg, 1998).

Is Passionate Love a Cultural Universal?

Since Darwin's classic treatise on *The Descent of Man and Selection in Relation to Sex,* scientists have debated the universality of romantic love. Once, scientists assumed that passionate love was a Western phenomenon. Today, most assume it to be a cultural universal. In one study, anthropologists selected a sampling of tribal societies from the *Standard Cross-Cultural Sample.* They found that in far-flung societies, young lovers talked about passionate love, recounted tales of love, sang love songs, and talked about the longings and anguish of infatuation. When passionate affections clashed with parents' or elders' wishes, young people often eloped. It appears that romantic love *is* a pan-human characteristic (see Jankowiak, 1995). However, cross-cultural researchers, anthropologists, and historians

point out that there is cultural variability in how common such feelings are.

Do Men and Women in Different Cultures Differ in Their Views of Love?

Culture has been found to have a significant impact on how men and women view passionate love. Researchers interviewed young people in America, Italy, and the People's Republic of China about their emotional experiences. They found that in all cultures, men and women identified the same prototypic emotions—joy/happiness, love/attraction, fear, anger/hate, and sadness/depression. Men and women also agreed as to whether emotions were positive experiences (such as joy) or negative ones (such as fear, anger, or sadness). The only exception was in the case of love. Americans and Italians tended to equate love with joy and happiness. Chinese students had a darker view of passion, associating it with sadness, pain, and heartache.

What Do Men and Women Desire In Romantic Partners, Sexual Partners, and Mates?

Throughout the world, young men and women desire many of the same things in a mate. In one cross-cultural study, Buss (1994) asked over 10,000 men and women from 37 countries to indicate what they valued in mates. The cultures represented a tremendous diversity of geographic, cultural, political, ethnic, religious, racial, economic, and linguistic groups. Of utmost importance was love! High on the list of things men and women cared about were character, emotional stability and maturity, a pleasing disposition, education and intelligence, health, sociability, a desire for home and children, refinement, good looks, and ambition.

Scientists have documented that a major determinant of sexual "chemistry" is physical attractiveness. People also tend to fall in love with people who are similar to themselves in attitudes, religious affiliation, values, interests, education, and socioeconomic status.

Do Men and Women Desire the Same Thing in Mates?

Evolutionary psychologists argue that there are major differences in what men and women desire in romantic partners and mates. An animal's "fitness" depends on how successful it is in transmitting its genes to subsequent generations. It is to both men's and women's evolutionary advantage to produce as many progeny as possible. Men and women differ, however, in "ideal" reproductive strategies: men seek quantity, women quality in a mate if they are to maximize reproductive outcomes. This logic led Buss (1994) to propose a "sexual strategies theory" of human mating. Men and women, he argues, are genetically programmed to desire different traits in potential mates. Men prefer women who are physically attractive, healthy, and young, and they desire sexual encounters with a variety of partners. Women seek out men who possess status, power, and money; who are willing to make a commitment; who are kind and considerate; and who like children. Buss and his colleagues have collected considerable evidence in support of these hypotheses.

Many anthropologists, historians, sociologists, and psychologists have sharply criticized the evolutionary approach. They point out that *Homo sapiens* possess an unrivaled ability to adapt—to change themselves and their worlds. Men and women possess different attitudes, these critics continue, not because they are propelled by ancient genetic codes, but because they are responding to different sociocultural realities. For most of human history, men and women who desired passionate liaisons and/or indulged in casual sex were likely to face very different consequences. Is it surprising, then, that even today many women fear risky sexual experiments?

There is evidence from nonhuman primates and from women in societies with few coercive constraints on female sexual behavior, such as the ¡Kung San or modern Scandinavia, that under permissive conditions women are far more active and assertive sexually and far more excited by sexual variety.

Is Passionate Love an Intensely Pleasurable or an Intensely Painful Experience?

For centuries, theorists have bitterly disagreed over what passionate love "really" is. Is it an intensely pleasurable experience or an intensely painful one? Some psychologists argue that passionate love is explained by the same reinforcement principles that explain interpersonal attraction in general. They contend that passionate love is stimulated by intensely positive experiences and dampened by intensely negative ones.

Other theorists take the opposite tack. They argue that passion can be fueled by admiration for a social ideal, a desire to expand one's horizons, a yearning for challenge, mystery, and excitement . . . and sometimes even anger and hostility (see Aron & Aron, 1986). Most social psychologists would probably agree that both pleasure and pain can fuel passion. They would endorse the old adage: "The opposite of love is not hate but indifference."

There are physiological reasons why love might be linked to both pleasure and pain. Physiologically, love, delight, and pain have one thing in common—they are intensely arousing. Joy, passion, and excitement as well as anger, envy, and hate all produce a sympathetic response in the nervous system. This is evidenced by the symptoms associated with all these emotions: a flushed face, sweaty palms, weak knees, butterflies in the stomach, dizziness, a pounding heart, trembling hands, and accelerated breathing. For this reason, theorists point out that either delight or pain (or a combination of the two) should have the potential to fuel a passionate experience.

An abundance of evidence supports the commonsense contention that, under the right conditions, intensely positive experiences such as euphoria, sexual fantasizing, an understanding partner, or general excitement can fuel passion. But there is also some evidence for the more intriguing contention that under the right conditions, anxiety and fear, jealousy, loneliness, anger, or even grief can fuel passion (see Hatfield & Rapson, 1993; Zillmann, 1998).

Strange as it sounds, then, evidence suggests that adrenalin makes the heart grow fonder. Delight is surely the most common stimulant of passionate love, yet anxiety and fear can sometimes play a part.

LURIA–NEBRASKA NEUROPSYCHOLOGICAL BATTERY

The Luria–Nebraska Neuropsychological Battery is a neuropsychological assessment battery based on the psychological procedures originated by the Russian neuropsychologist Alexander R. Luria, and subsequently reorganized by Charles J. Golden (Golden, Hammeke, & Purisch, 1978) and his associates into a standardized battery of Luria's tests for the purpose of clinical neurodiagnosis. Luria, like the English neurologist J. Hughlings Jackson and his fellow Russian L. S. Vygotsky, believed that brain–behavior relationships could not be explained satisfactorily by either the localizationist or the equipotentialist theories of brain function. Instead, Luria conceived of behavior as the result of the interactions among all areas of the brain, and favored the use of simple test procedures that reflected relatively uncomplicated patterns of brain interactions, so that functional systems of the brain could be more precisely investigated.

Recognition of Luria in the United States came with the publication of *Higher Cortical Functions in Man* (1962) and *The Working Brain* (1973). Detailed information on Luria's test procedures became available with Anne-Lise Christensen's (1979) *Luria's Neuropsychological Investigation.* Luria's testing methods were not immediately accepted by American clinical neuropsychologists because of the absence of a standardized, quantitative scoring system and of experimental evidence supporting the validity of the test procedures. In addition, Luria's procedures appeared to rely heavily upon clinical judgment rather than objective, verifiable data.

To remedy the psychometric deficits of the Luria techniques, Golden and his colleagues transformed Luria's test items into standardized test procedures with objective scoring systems, and a battery that allowed a clinical evaluation on a quantitative level, like most American tests, as well as a qualitative level, as urged by Luria. The standardized version of Luria's tests assesses major areas of neuropsychological performance, including motor, tactile, and visual skills; auditory abilities; expressive and receptive speech functions; reading, writing, and arithmetic abilities; spatial skills; and memory and intelligence.

Description of the Battery

There are 269 items in the standardized Luria battery, initially referred to as the Luria–South Dakota Neuropsychological Test Battery. Each item is a test of a specific aspect of neuropsychological functioning. Subgroups of items exist which represent performance in the content area implied by the name of the scale, as, for example, the motor functions scale. The names of the scales of the Luria–Nebraska Neuropsychological Battery are as follows:

1. Motor Functions
2. Rhythm (acoustico-motor) Functions
3. Tactile (higher cutaneous and kinesthetic) Functions
4. Visual (spatial) Functions
5. Receptive Speech
6. Expressive Speech
7. Writing Functions
8. Reading Skills
9. Arithmetical Skills
10. Memory
11. Intellectual Processes

Form II of this battery added a twelfth scale, Intermediate Memory, which assesses delayed recall of 10 of the previously administered Memory items.

There are five summary scales, based on some of the items of the clinical scales:

1. Pathognomonic. This scale consists of simple items rarely missed by normals and is highly indicative of brain dysfunction.
2. Right Hemisphere. This scale measures the motor and tactile functioning of the left side of the body.
3. Left Hemisphere. This scale measures the motor and tactile functioning of the right side of the body.
4. Profile Elevation. This scale measures the level of present functioning or degree of behavioral compensation.
5. Impairment. This scale measures the degree of overall impairment.

Since the original publication of this battery, other scales have been developed, including eight localization scales (Frontal, Sensorimotor, Parietal-Occipital, and Temporal scales for each brain hemisphere) and 28 separate factor scales. A 66-item list of qualitative descriptors of test performance is also provided to aid the examiner in evaluating the nature of performance errors.

An impaired performance on any of the scales is determined by comparison with a critical level, which is calculated for each patient with age and education corrections. If a scale exceeds the critical level, the possibility of impairment on that scale is suggested. Two or more scales exceeding the critical level are suggestive of brain damage.

An adaptation for children, The Luria–Nebraska Neuropsychological Battery—Children's Revision, is available for ages 8 to 12. A short form of this battery has been proposed to be used with elderly patients.

The Luria–Nebraska is administered by psychologists as well as by psychology technicians trained in the administration and scoring procedures of the battery. The testing time averages about 2½ hours. The scale scores can be hand-scored, but a computerized service by the test battery's publisher is also available.

Neuropsychological Studies

Several validity studies of the Luria–Nebraska have been completed using normal, brain-damaged, and schizophrenic patients. In 1978, Golden, Hammeke, and Purisch reported the first validity study of the Luria, examining the test items with 50 brain-damaged and 50 control subjects. Of the 269 Luria items, 252 were found to discriminate significantly at the 0.05 level or better, with the remaining 17 items significant at the 0.02 level.

Hammeke, Golden, and Purisch (1978) also studied the 14 scales of the Luria Battery with 50 brain-damaged subjects and 50 controls. The diagnostic accuracy of the scales with the brain-damaged subjects ranged from 64% for the Arithmetic Scale to 86% for the Expressive Speech Scale. The hit rates with the normal subjects ranged from 74% for the Expressive Speech Scale to 96% for the Memory Scale. A discriminant analysis using the 14 scaled scores correctly classified all 50 control patients and 43 of the brain-damaged patients, yielding an overall hit rate of 93%.

Cross-validation of the standardized Luria was reported by Golden, Moses, and colleagues (1981), utilizing 87 patients with localized lesions and 30 control patients. A Luria–Nebraska summary score led to an 74% accuracy rate for determining brain damage. The two hemisphere scales yielded a lateralization hit rate of 78%, whereas the highest localization scale led to a lateralization hit rate of 92% and a localization hit rate of 84%.

The effectiveness of the Luria–Nebraska was compared with the Halstead-Reitan Neuropsychological Battery, recognized as the most widely used standardized battery. Both test batteries were administered to 48 brain-damaged and 60 normal subjects. The results showed a high degree of relationship (all Rs > 0.71, $p < 0.05$) between the 14 Luria–Nebraska scale scores and the major 14 scores of the Halstead-Reitan. Discriminant analysis found both batteries equally effective in identifying the brain-damaged subjects, with hit rates over 85% (Golden, Kane, et al., 1981).

Critique of this battery has noted that it is comprised of test items from Luria's work, but it does not necessarily represent Luria's clinical and qualitative methodology of testing hypotheses concerning a patient's neuropsychological functions or deficits. Support for the battery, on the other hand, has identified the standardization and empirical aspects of this battery as its strongest assets (Anastasi, 1982). Although the validity of this battery with neurologically impaired patients has been confirmed by a number of studies by Golden and his associates, others have been unable to replicate these validation findings. A frequent source of diagnostic errors occur with patients experiencing language impairment, evidently due to the highly verbal nature of many of the test items.

A concise review of this battery is presented in Lezak's (1995) *Neuropsychological Assessment,* including a discussion of concerns about the battery's norms, scale specificity, validation studies, and lateralization capabilities.

MAGNETIC RESONANCE IMAGING (MRI)

Magnetic resonance imaging (MRI) is a method that can provide information on both the anatomy and physiological function of the brain. It is a powerful tool for integrating our current understanding of brain function with models of cognition and emotion. *Anatomical MRI* provides a picture of brain structure, whereas *functional MRI* (fMRI) provides information about the physiological function of the brain.

MRI relies on three magnetic fields. A constant magnetic field, known as the static field, aligns all magnetically sensitive particles uniformly, so that perturbations can be detected. In clinical machines, this magnetic field is generally between 0.5 and 1.5 tesla (T) and in "high-field" research machines, it is either 3 or 4 T (as reference, the magnetic field of the earth is 0.0001 T). The perturbation is supplied by a second magnetic field, known as the pulse sequence, which is an oscillating electromagnetic field "tuned" to a set frequency (resonant frequency) of a particular substance, typically hydrogen atoms. The relaxation time, the time it takes for the protons to revert to their original state, is recorded through a radio frequency coil, also known as a receiver coil. Because hydrogen atoms in different substances have different relaxation times, distinct tissues, such as white matter and gray matter, can be differentiated. Information on where in the brain those substances are residing comes from another magnetic field, the gradient field, which varies in intensity over the area being imaged.

Standard anatomical MRI can be used to examine the structural integrity of different brain regions. For example, it can detect reduced cerebral volume with aging or increases in myelination during childhood. Recently developed *diffusion tensor MRI* (DTMRI) provides information about the structural integrity of nerve fibers as well as patterns of anatomical connectivity. This method works by detecting differences in the degree to which water diffuses along each of the three axes of nerve fibers. The axis along which water diffusion is greatest indicates the main directional orientation of white matter tracts, while the degree of diffusion can provide information on the structural integrity of those tracts. Because white matter tracts connect distant brain regions, this method can be utilized to detect disorders that arise from a partial or complete disconnection between brain regions.

Functional MRI (fMRI) detects local changes in other physiological functions, such as cerebral blood flow and blood oxygenation. The most commonly used fMRI method, known as BOLD (Blood Oxygen Level Dependent), takes advantage of the fact that oxygenated blood is more magnetic than deoxygenated blood. Neuronal activity causes a local increase in oxygen-rich blood. Because the local tissue cannot extract all the oxygen supplied, the relative proportion of oxygenated blood to deoxygenated blood increases in that region. This change results in an increased signal from which a measure of brain activation can be derived.

Because we are detecting a change in the signal, fMRI always requires that two conditions be compared: the condition of interest and a baseline condition. The selection of the baseline is critical for interpretation of the results. For example, to determine those regions specifically involved in processing the emotional information contained in faces, brain activation while viewing emotional faces needs to be compared to a baseline of brain activation while viewing nonemotional faces. On the other hand, if the desire is to determine all the brain regions involved in processing emotional faces, then brain activation while viewing emotional faces needs to be compared to a baseline of brain activation while viewing a simple visual stimulus, such as a series of crosses.

The creation and use of fMRI techniques, although burgeoning, are still in the developmental stage. Currently, other fMRI methods such as arterial spin-labeling techniques are being developed and advanced in the hope that they will provide a powerful method of measuring cerebral blood flow. Absolute measures of cerebral blood flow are advantageous because they allow for direct comparisons across individuals, such as younger individuals and older individuals.

fMRI is very useful for a number of reasons. First, it is widely available and can be performed on clinical MRI machines that have been appropriately upgraded to enable these methods. Second, it is a noninvasive technique and does not involve high-energy ionizing radiation. Third, multiple scans can be run on a single individual, allowing clinicians and scientists to examine changes in the brain over time, such as those that occur as a result of practice or treatment regimens. Fourth, it provides superior temporal and spatial resolution relative to other brain imaging methods, such as positron emission tomography (PET). fMRI allows brain activity to be detected in seconds and with an anatomical resolution of 3 to 5 millimeters.

Because MRI can be tuned to specific atoms, it can be utilized to examine the concentration of other biologically-active substances via a method known as *magnetic resonance spectroscopy.* This method is limited in that it provides only very gross information on the location of such substances within the brain (e.g., within the frontal lobe), and cannot be used unless the concentration of the substance is quite high. For example, it remains to be seen whether this method will be able to detect neurotransmitters. One substance examined using this technique is *N*-acetylaspartate (NAA), an amino acid found in high concentration within the nervous system. Reduced NAA is observed when neuronal functioning is less than optimal, such as occurs when pathological processes are acting upon neurons or when the energy metabolism of the brain is compromised. For example, lower levels of NAA in the dorsolateral prefrontal cortex of schizophrenics are associated with poorer cognitive abilities on a test of executive function. The importance of magnetic resonance spectroscopy may increase in the future as high-field MRI systems become more commonplace, and as greater field strength enhances the ability to detect substances at lower concentrations.

MAINSTREAMING

Mainstreaming dates back to the very beginnings of the field of special education. As the term implies, mainstreaming means educating students with disabilities alongside "typical" students in a general education classroom for at least some portion of a school day. Mainstreaming came into widespread use in the late 1960s as professionals and parents called into question the segregation of students with disabilities in U.S. public schools. Professionals argued that special classes for students, particularly those with mental retardation, could not be justified. The purpose of mainstreaming was to ensure that students with disabilities received individualized planning and support from both general and special education teachers. However, this did not always happen in actual practice. In fact, the term *mainstreaming* fell out of favor when it became associated with placing students with disabilities in general education classes without the necessary support. It was viewed by parents as a means to save money and limit the number of students who could receive specialized services. Such practices gave rise to the term *maindumping.* Although the term *mainstreaming* remains in limited use today as one way to describe educating students with disabilities in general education settings, other descriptors have come into popular use, including *integration, least restrictive environment,* and *inclusive education.*

With the passage of the federal Education of All Handicapped Children Act of 1975 (now the Individuals with Disabilities Education Act [IDEA]), *least restrictive environment* (LRE) became a commonly used term in the United States. LRE describes a process by which students with disabilities are placed in educational settings consistent with their individual educational needs. As defined in IDEA, the intent of LRE is to educate students with disabilities with their typical peers to the maximum extent appropriate. A student is removed from the general education setting only when the nature and severity of the disability are such that education in general education classes with supplementary aids or services cannot be satisfactorily achieved.

Although the concept of LRE suggests a strong preference for students with disabilities to be educated alongside their typical peers, it also states that this should occur only when appropriate. As such, LRE and mainstreaming are not synonymous. A student's LRE may be any one of a "continuum of placements," ranging from the general education classroom to separate educational environments exclusively for students with disabilities. Public schools are required to provide such a continuum for students who cannot be satisfactorily educated in general education classes. Whenever possible, however, students should be educated in or close to the school they would attend if not disabled.

As with mainstreaming, the concept of LRE has been criticized in recent years. The concern is that, despite LRE's strong preference for students to be educated with their typical peers, it also has legitimized and supported the need for more restrictive, segregated settings. Additionally, LRE has created the perception that students with disabilities must go to services, rather than having services come to them. In other words, as students move further from the general education classroom, the resources available to meet their needs increase accordingly.

Whereas LRE is the term most often associated with special education in the United States, *integration* is the term that is most often used to describe programs and services in several other countries. For example, Italy's laws mandate the integration of students with disabilities into general education classes. Australia may be described as moving toward full integration of these students, while to a lesser extent France, England, and Germany all have major initiatives promoting the integration of students with disabilities into general education settings.

In the United States, the term integration is most closely associated with social policy to end separate education for ethnic minority children, specifically students of color. In the landmark *Brown v. Board of Education* in 1954, the U.S. Supreme Court ruled that education must be made available to everyone on an equal basis. Separate education for African-American students was ruled inherently unequal to that of white students. The increasing use of the

term *integration* by many professionals and parents to describe the value of educating students with disabilities alongside their typical peers coincided with the U.S. civil rights movement of the 1980s for people with disabilities, a movement that culminated in the passage of the Americans with Disabilities Act (ADA) in 1990. In fact, ADA moved away from the concept of the least restrictive environment as defined in IDEA, mandating that people with disabilities be placed in integrated settings appropriate to their individual needs.

In today's schools, the most widely used term consistent with the original intent of mainstreaming is *inclusive education.* At its most fundamental level, inclusive education promotes the value of students with disabilities attending the same school they would attend were they not disabled. This approach promotes acceptance and belonging, focusing on services and support coming to students within the setting of the general education school and classroom, rather than students with disabilities going to services in a segregated environment. In inclusive classrooms, the intent is for all students to be actively involved, socially accepted, and motivated to learn to the best of their ability.

To achieve this goal, some professionals have argued for specific changes in the educational system. These include providing inclusive services and support in "neighborhood" schools. The proportion of students needing special education should be relatively uniform for all schools within a particular area or district, and should reflect the proportion of people with disabilities in society at large. In such neighborhood schools, students with disabilities could receive the support they need to succeed without being segregated into special classes within the school.

Inclusive education may be defined by the level of participation and support available to the student in the educational setting. Two terms describe these levels: *full inclusion* and *partial inclusion.* Full inclusion is an approach whereby students with disabilities receive all instruction in a general education classroom setting; support services come to the student. With partial inclusion, students with disabilities receive most of their instruction in general education settings but are "pulled out" to another instructional setting when appropriate to their individual needs.

The success of both full and partial inclusion programs depends on the availability of both formal and natural supports in the general education classroom. Formal supports are those provided by, and funded through, the public school system. These include qualified teachers, paraprofessionals, appropriate curriculum materials, and assistive technology aids. Natural supports in an educational setting most often consist of the student's family and classmates. Natural supports emphasize the relationship among children as friends and learning partners.

MAJOR DEPRESSIVE DISORDER: RECOVERY AND RECURRENCE

Major Depressive Disorder

Major Depressive Disorder (MDD) is characterized by depressed mood or a lack of interest or pleasure in once-enjoyable activities, and associated symptoms (e.g., sleep disturbance, appetite/weight disturbance, difficulty concentrating, worthlessness or exaggerated guilt). To receive a diagnosis of MDD, at least five symptoms must be present most of the day, nearly every day, for at least 2 weeks (American Psychiatric Association [ApA], 1994).

The lifetime and 12-month prevalence of MDD is higher than that of any other major psychiatric disorder (Kessler et al., 1994), and evidence suggests that the prevalence of MDD has been increasing in recent birth cohorts (Lewinsohn, Rohde, Seeley, & Fischer, 1993) while the age at first onset has been decreasing (Klerman & Weissman, 1989). Indeed, approximately 25% of entering college students have previously experienced an episode of MDD (Lewinsohn, Clarke, Seeley, & Rohde, 1994). Although episodes of MDD appear to be self-limiting, the disorder is typically episodic, with high rates of relapse/recurrence.

Remission and Recovery

Over the years, researchers have used various definitions of "remission" and "recovery" from MDD. Guidelines published in recent years (Frank et al., 1991) have increased consistency across studies. There is now some agreement that remission is a period during which full criteria for MDD are no longer met but significant symptoms remain (partial remission), or during which the individual experiences no more than minimal (e.g., two or fewer) symptoms for up to 6 months (full remission). Full recovery is defined as 6 months or longer with no more than two symptoms.

An episode of major depression appears to be self-limiting, in that most cases remit in approximately 6 to 8 months, even if untreated. Recovery rates appear to be similar across children and adult samples. For example, Kessler and Walters (1998) found that, in a community sample of adolescents and young adults, the average length of the longest episode an individual had suffered was 32.5 weeks. Similarly, Kovacs and colleagues (1984a) reported a mean length of 32 weeks for a sample of depressed children. Within 1 year of onset of a major depressive episode, 78% of adults will have recovered (Keller, Lavori, Rice, Coryell, & Hirschfeld, 1986).

Despite the high rate of spontaneous remission of MDD and an average length of six to eight months per episode, a number of individuals suffer significantly longer episodes of depression. While 78% of depressed adults remit within 1 year of onset of MDD, 22% experience a more chronic course. The longer an individual suffers from an episode of MDD, the lower the probability of recovery from that epi-

sode. Thus, for individuals who have not recovered within one to two years of onset, the prognosis is relatively poor. The long-term prognosis for individuals who recover more quickly from MDD is also discouraging, in that a large proportion will suffer a relapse or recurrence of the disorder.

Relapse and Recurrence

Relapse is a return of symptoms such that the individual once again meets full criteria for MDD during the period of remission but before recovery. A recurrence, in contrast, is a new episode of MDD with onset occurring after full recovery from the previous episode (Frank et al., 1991). Although these terms have been defined fairly consistently in recent research, much of the earlier research did not differentiate between relapse and recurrence; therefore, these terms will be used interchangeably here.

A recent review of the literature revealed that more than 50% of adults who recover from an episode of MDD again meet criteria for MDD within 3 years of the index episode (Brosse, Craighead, & Craighead, 2002). More specifically, the recurrence rate in adult outpatient samples was found to be 19% to 32% at 1-year follow-up, 36% to 38% after 18 months, 21% to 44% after 2 years, and 43% at 30-months follow-up. In adult samples comprised of both outpatients and inpatients, 24% to 36% experienced a recurrence within 6 months of recovery, increasing to 37% to 40% after 10 to 12 months, 52% by 26 months, 57% by 3 years, 71% by 5 years, and 85% by 15-year follow-up. The highest recurrence rates were reported for inpatient samples. Between 25% and 43% recurred within 6 months of recovery, a rate not achieved in outpatient samples until 18 months after recovery; 51% suffered a recurrence within 9 months, 27% to 55% within 1 year (with only one study reporting a rate lower than 41%), and 54% to 68% within 2 years. Similar rates of relapse and recurrence have been found in children and adolescents with MDD (e.g., Kovacs et al., 1984b).

It appears that each new MDD episode increases the risk of suffering yet another episode (ApA, 1994); additionally, there is some evidence of increasing severity with each new MDD episode, as well as decreased well time between episodes. Preliminary evidence suggests that acute treatment with psychotherapy (e.g., cognitive behavior therapy, interpersonal psychotherapy) provides greater prophylactics against relapse than does pharmacotherapy, and that "maintenance" or "continuation" psychotherapy further protects patients against relapse (e.g., Jarrett et al., 2001). Given the high cost of depression, and the increasing severity of the disorder with each new episode, additional research regarding the prevention of relapse and recurrence of MDD is clearly warranted.

MALE SEXUAL DYSFUNCTION

Male Erectile Disorder

Since the advent of pharmacological treatment for male erectile disorder and the ensuing flood of print and televi-

sion ads, this disorder has become the definitive example of sexual disorders that affect men. Male Erectile Disorder (ED) is defined by an inability to attain or maintain an erection until completion of sexual activity, and is associated with marked distress or interpersonal difficulty (American Psychiatric Association [ApA], 2000). Epidemiological studies have not typically included assessment of sexual disorders, but sex researchers who have studied the prevalence of ED in community samples have found rates ranging from 3% to 9% of men of all ages (Spector & Carey, 1990).

Studies of prevalence in men from ages 40 to 70 have found that approximately 52% of males in this age range experience mild, moderate, or severe erectile difficulties (Feldman, Goldstein, Hatzichristou, Krane, & McKinlay, 1994). Previous estimates of ED complaints in clinical samples have indicated that from 36% to 48% of men who present for treatment in sex clinics have a primary diagnosis of male erectile disorder (Ackerman & Carey, 1995). Current estimates of clinical prevalence are missing, and may be important in describing the change in treatment for erectile dysfunction from sex therapy to pharmacology. Physiologically-based risk factors for ED include older age, alcohol use, nicotine use, and a sedentary lifestyle (Ackerman & Carey, 1995; Tengs & Osgood, 2001). Psychological risk factors include mental disorders and acute emotional states, particularly anxiety and depression (Barlow, 1986; Masters & Johnson, 1970; Wincze & Carey, 1991).

Assessment of ED and its etiological source has long been considered a difficult undertaking for clinicians. Historically, erectile dysfunction was considered a purely psychological disorder that should be treated with traditional behavioral sex therapy techniques (Ackerman & Carey, 1995). More recently, clinical attention has been focused on issues of differential diagnosis and determining the relative importance of psychogenic and organic factors in the etiology and persistence of erection difficulties. Physiological problems such as neurological diseases, hormonal abnormalities, and vascular problems are involved in a considerable percentage of ED cases, with or without corresponding psychological origins (Tanagho, Lue, & McClure, 1988). Many medications have also been implicated in causing erectile difficulty, including the SSRI's (Rosen, Lane, & Menza, 1999).

Psychogenic contributions to ED include the emotional states mentioned earlier as well as dysfunctional cognitions about sexual performance (Cranston-Cuebas & Barlow, 1990; Masters & Johnson, 1970; Weisberg, Brown, Wincze, & Barlow, 2001) and dyadic relationship problems (Leiblum & Rosen, 1988). In addition, a lack of adequate penile stimulation during foreplay, typically a necessary component of erectile attainment in aging males, has been indicated in some mild impairments of functioning (Meggers & LoPiccolo, 2002). Determining the etiological source of ED for each individual requires a medical examination as well as an assessment of psychological factors that play a role in both cause and persistence of problems. As noted by LoPiccolo (1994), the presence of organic impairment does not always negate the need for behavioral treatment. In many cases, men with mild organic impairment are made more vulnerable to erectile failure by psychological, behavioral, and sexual technique factors.

Several medical treatment strategies for ED have been utilized in the past, including penile implants, vacuum devices, and penile injections. The most recent advance in the medical treatment of ED, however, is the medication sildenafil, better known by its trade name, Viagra. Viagra is an effective treatment, showing positive results in 70 to 80 percent of cases treated (Sadovsky et al., 2001). The drug works by reducing venous outflow once blood has been pumped into the cavernous bodies, *not* by increasing arterial inflow. As a result, men who use Viagra still need adequate sexual and emotional stimulation to achieve an erection. Some of the 20 to 30 percent of cases in which Viagra fails are not actually pharmacologic failures, but failures to provide adequate physical or emotional stimulation. Consequently, the use of Viagra is contraindicated in instances where couple systemic issues are the only etiological factors contributing to erectile difficulties. In addition, Viagra is also contraindicated in instances where low desire is the cause of erectile failure, as the drug has not been shown to increase levels of desire.

The predominant themes in the psychological treatment of erectile dysfunction are the reduction of performance anxiety and the increase of sexual stimulation, and this treatment approach is still based largely on the work of Masters and Johnson (1970). One comprehensive study of treatment outcome research for male sexual dysfunctions reported that there is a paucity of well-designed studies to determine the effectiveness of behavioral sex therapy for male erectile disorder (O'Donohue, Swingen, Dopke, & Regev, 1999). However, behavioral sex therapy for ED is included on the list of empirically supported treatments compiled by ApA's Task Force on Promotion and Dissemination of Psychological Procedures (1995).

Premature Ejaculation

While ED is typically a dysfunction of older males, Premature Ejaculation (PE) most frequently occurs in younger men. PE is the persistent or recurrent ejaculation during sexual activity that is associated with minimal stimulation and individual or couple dissatisfaction with duration (ApA, 2000). At the present time, there are no objective criteria for determining the duration of sexual activity that constitutes premature ejaculation. Perhaps it is easier to describe what is not premature ejaculation: Both partners agree that the quality of their sexual activities is not negatively impacted by efforts to postpone ejaculation (LoPiccolo, 1994). Prevalence estimates for PE derived from community samples indicate a rate of disorder between 36 and 38% (Spector & Carey, 1990).

Definitive data on the etiology of premature ejaculation

does not currently exist. Sociobiologists have theorized that it offers an evolutionary advantage and has been built into the human organism (Hong, 1984). However, this theory does not effectively deal with the large variability in duration of intercourse that has been observed both across and within species. Another theory proposed by Kaplan (1974) postulates that men with premature ejaculation are not able to accurately perceive their own level of sexual arousal and thus do not engage in any self-control procedures to avoid rapid ejaculation. One laboratory analogue indicates, however, that men with premature ejaculation were better able to perceive their own levels of sexual arousal when compared to controls (Spiess, Geer, & O'Donohue, 1984).

Rowland, Cooper, and Slob (1996) found that men who experience PE can be differentiated from functional men and men with ED by both a heightened response to vibrotactile penile stimulation and an increase in negative emotion, such as shame and embarrassment, during sexually arousing activities. This evidence supports a psychophysiological model of PE in which a vulnerability of the penile reflex and intensified negative cognitions and affect combine to create problems with ejaculation latency (Strassberg, Kelly, Carroll, & Kircher, 1987). Finally, it has been proposed that premature ejaculation is related to low frequency of sexual activity (Kinsey, Pomeroy, & Martin, 1948). While some research has indicated that sensory thresholds in the penis are lowered by infrequent sexual activity and that premature ejaculation patients do have a low rate of sexual activity (e.g., Spiess et al., 1984), it is possible that premature ejaculation causes low rates of sex, rather than causality being in the opposite direction, as this disorder makes sex an unpleasant failure experience.

The standard treatment for PE involves the pause procedure developed by Semans (1956) and modified into the pause and squeeze technique by Masters and Johnson (1970). Although there has not been a controlled experimental study of the relative effectiveness of the pause procedure versus the pause and squeeze technique, both appear to be effective. Success rates of 90% to 98% "cure" have been reported, and this success has been demonstrated in group and individual treatment as well as in self-help programs (Kilmann & Auerbach, 1979).

More recently, psychopharmacological treatment of PE has been the subject of research. According to Rosen et al. (1999), several uncontrolled studies of SSRI treatment of PE have indicated that pharmacological treatment may be efficacious. Waldinger, Hengeveld, and Zwinderman (1994) found that low doses of clomipramine significantly improved ejaculatory latency and improved sexual satisfaction in men with PE. Similar results have been found for paroxetine, fluoxetine, and setraline (Rosen et al., 1999). While SSRI treatment for PE seems provocative, it is important to remember that serotonergic drugs have well-known deleterious effects on sexual arousal and physicians and clinicians should question whether reducing levels of sexual arousal is a desirable method for lengthening ejaculatory latencies. SSRI treatment of PE is temporary, with latency effects disappearing after treatment is discontinued (Waldinger et al., 1994).

Hypoactive Sexual Desire Disorder (HSDD)

HSDD is a disorder characterized by absent or low desire for sexual activity that is associated with interpersonal difficulty or distress (ApA, 2000). A distinction is made between receptive and proceptive sexual behaviors, with a lack of proceptive behavior most indicative of true low sexual desire (Pridal & LoPiccolo, 2000). HSDD affects both men and women, and it is the most common primary diagnosis in cases of sexual dysfunction. Segraves and Segraves (1991) conducted a large pharmaceutical study for sexual disorders and found that 19% of clients with a primary diagnosis of HSDD were male. Prevalence estimates for community samples indicate a rate of 15% for males (Rosen & Leiblum, 1995).

The three major etiological factors for low sexual desire that have been proposed are hormonal problems, affective-cognitive models, and relationship dynamic theories. Although evidence of hormonal influence on sexual desire in females is inconsistent, research continually shows a relationship between androgens and sexual desire in males (Beck, 1995). Androgens, particularly testosterone, seem to be essential for normal levels of sexual desire in males (Bancroft, 1988). However, testosterone deficiency does not account for all cases of HSDD in males (Schover & LoPiccolo, 1982).

Theories of excessive negative affect may account for some of these non-physiological cases. Kaplan's (1979) theory of intrapsychic anxiety and anger as determinants of low desire has also received empirical support. Studies indicate that increased anger is associated with diminished desire and penile tumescence in men, while anxiety is related to decreased subjective arousal but is not related to tumescence (Beck & Bozman, 1995; Bozman & Beck, 1991).

Relationship dynamic explanations for low drive in men have stressed the adaptive value of low desire for the maintenance of relationship equilibrium (LoPiccolo & Friedman, 1988; Verhulst & Heimen, 1988). Low desire may serve an effective function within the habitual dynamics of the marital relationship. For example, low drive is cited as being a passive-aggressive way for a man to maintain a position of some power and control or emotional distance in a relationship. Finally, it is necessary to mention briefly the adverse effects of many medications on sexual desire, including antihypertensives and psychotropic medications—particularly SSRIs (Rosen et al., 1999).

Low sexual desire has been seen with increasing frequency in clinical practice. In fact, attenuated desire is now the most common complaint among patients seeking therapy (LoPiccolo & Friedman, 1988). However, treatment for low sexual desire can be a complex issue, as people with low sexual desire often have even lower levels of desire for ther-

apeutic intervention. Perhaps because of this, quality treatment outcome measures for low drive are relatively scarce (see O'Donohue et al., 1999). However, some studies have demonstrated good treatment results using a complex, cognitive-behavioral treatment program (LoPiccolo & Friedman, 1988) with a focus on low desire symptomatology (Schover & LoPiccolo, 1982). This focus on specific symptoms is seen as imperative to the success of treatment of low desire, as standard sex therapy often fails to raise desire (Kaplan, 1979).

Male Orgasmic Disorder

Male Orgasmic Disorder, previously referred to as Inhibited Ejaculation, has received very little attention in the therapeutic literature. As initially reported by Masters and Johnson (1970), this remains a relatively rare dysfunction, and etiology remains unclear. Clinical case studies suggest a variety of psychological factors as causes, but there is virtually no empirical support for these theories (Dow, 1981; Schull & Sprenkle, 1980). Male Orgasmic Disorder can, however, result from a number of physiological conditions, such as multiple sclerosis and damage to the hypothalamus. Finally, the inability to reach orgasm may be a side effect of several medications, including anti-hypertensives; sedatives; and anti-anxiety, anti-depressive, and antipsychotic agents (Ban & Freyhan, 1980).

Perhaps due to the ambiguity surrounding the etiology of Male Orgasmic Disorder, relatively little has appeared in the literature regarding treatment. The standard treatment strategies—eliminating performance anxiety and ensuring adequate stimulation—remain the preferred treatment approaches (LoPiccolo, 1994). Additional elements taken from the treatment program for female anorgasmia, including the use of vibrators, certain behavioral maneuvers, and patient role-play of an exaggerated orgasm, also seem to have some success in treating males (LoPiccolo, 1977). For cases caused by organic impairment, some success has been reported with the use of drugs, such as ephedrine sulfate, that work to activate the sympathetic nervous system (Murphy & Lipshultz, 1988). In addition, behavioral modification that leads to increased stimulation of the scrotal, perineal, and anal areas also tends to trigger orgasm. The use of an anal insertion probe is the most effective technique for inducing orgasm and, in fact, is the only effective treatment for severely neurologically impaired patients (Murphy & Lipshultz, 1988).

MANAGED MENTAL HEALTH CARE

Managed care is any health care delivery method in which an entity other than the health care provider actively manages both financial and medical aspects of health care. It includes a wide variety of techniques, products, and services that integrate the financing and the delivery of health care. Based on the premise that providers alter practice in response to financial incentives, managed care was created to control the costs, use, and quality of health care by increasing provider accountability to payers, promoting competition, and using practice standards. Managed mental health care (behavioral services) can co-exist with or be delivered within general managed care health systems. Alternatively, they can be separated or "carved out" from general health care plans and contracted to specialized providers who are responsible for utilization control, provider selection, finances, and quality assurance.

Managed care began as prepaid health care, the provision of a set package of services for a pre-established fee. The originators intended to deliver affordable, accessible care to poor and middle-class farmers and laborers who wanted to eliminate unexpected medical bills. Today's critics of managed care say it has failed in this mission. They argue that consolidation of behavioral health care has concentrated control in the hands of a few powerful fiscal organizations. These organizations, say critics, place profit ahead of patient welfare, deny or delay access to necessary treatments and providers, award bonuses for reducing referrals to specialists, and arbitrarily discharge providers who use too many resources. For-profit, industrialized health care has not controlled inflationary medical costs, and over 42 million Americans are without health insurance.

Forms of Managed Health Care

Managed health care evolved swiftly from the 1980s to the present. Forms of managed care and managed mental

health care are defined according to: (1) structural characteristics, (2) relationship of provider and patients to systems, and (3) financial arrangements. Methods to reduce costs include reviewing the medical necessity of services, intensive management of high cost cases, regulation of inpatient admissions and length of stay, incentives for selecting less costly forms of care, beneficiary cost sharing, and selective contracting with health care providers. Hybrids blend the characteristics of more than one model as a function of diverse sets of local and regional requirements, state regulations, and specific statutes. The major types of managed health care are as follows:

1. *Utilization review and management* provides evaluation of medical necessity and appropriateness of mental health services prospectively, concurrently, or restrospectively.
2. The *Staff Model Health Maintenance Organization (HMO)* offers services to a defined population for a fixed price (capitation). Providers are salaried employees or contractors who work in specific locations.
3. In the *Independent Practice Association (IPA),* individual providers contract with an HMO to provide care in their own offices. Reimbursement is a prearranged fee-for-service, capitated, or percentage of the subscriber's premium. Providers contribute to risk pools, and hold-backs are incentives to control utilization.
4. *Group model HMOs* contract with groups of providers to devote a specified percentage of practice time to subscribers on a salaried or capitated basis, usually in a central location. Providers share in the group's profit or loss.
5. *Preferred Provider Organization (PPO)* caregivers must offer cost-effective care to a predetermined subscriber group for either discounted rates or a schedule of maximum payments in return for a certain volume of referrals. Consumers can use nonparticipating providers, but receive discounts for using PPO providers. An Exclusive PPO pays only for services from participating providers.
6. *Independent broker models* use a liaison between providers who want to sell and buyers (small business, the self-insured, guilds, etc.) who group together in order to purchase discounted services.
7. The *network model* combines features of the IPA, group and staff models, and contracts with HMOs to provide services. Providers do not provide care exclusively to HMO members and will give care to nonmembers.
8. A *point-of-service* or *open-ended plan* reduces fees or increases benefits to encourage the use of network providers.
9. In an *employee assistance program (EAP),* mental health services are provided to the employee in the workplace or off-site.
10. An *integrated delivery system (IDS)* has a variety of providers, such as a management service, medical foundation, group provider practice, and physician-hospital that work together to provide coordinated, comprehensive care for patient needs, including acute inpatient, outpatient, and prevention services.

MANAGEMENT DECISION MAKING

A major concern in management has been to understand and improve decision making. Psychologists have proposed various approaches, most based on a "divide-and-conquer" strategy. This strategy involves breaking a large problem into smaller parts. The idea is not new; Benjamin Franklin in a "Letter to Joseph Priestly" (1956) described such a decomposition strategy.

Nobel laureate Herbert Simon outlined the theoretical justification for this approach in his account of "bounded rationality." This concept says that cognitive processing limitations force humans to construct simplified mental models of the world. As Simon observed, a person "behaves

rationally with respect to this model . . . (although) such behavior is not even approximately optimal" (1957, p. 198).

There have been two approaches to accounts of management decision making. The first is concerned with development and application of normative decision rules based on formal logic from economics or statistics. The second involves descriptive accounts of how people go about making judgments and decisions.

Normative Analyses

As outlined in John von Neumann and Oskar Morgenstern's seminal 1947 book, *Theory of Games and Economic Behavior,* various techniques exist for making optimal decisions. A distinction is drawn between riskless (or certain) choices and risky (or uncertain) choices.

Multi-Attribute Utility

Multi-attribute utility (MAU) applies to decisions with riskless outcomes. MAU involves estimating utility values for decision alternatives and selecting the alternative with the highest value. The utility for an alternative is obtained from a weighted sum of the part utilities. The MAU approach has been applied to management decisions such as siting new plants and personnel selection.

Decision-Tree Analysis

A decision tree is a graphical model that displays the sequence of choices that make up a risky decision. The approach is based on laying out choice alternatives, uncertain events, and outcome utilities as a series of branches. For each alternative, an expected value (EV) is computed as the average outcome value over all events. The optimal choice is the alternative with the highest EV. Decision trees have been used to guide high-risk decisions such as new product marketing and public policy.

Bayesian Networks

Bayesian networks combine Bayesian probability theory, artificial intelligence, and graphical analysis into a decision-making analytic tool. Starting with a fully connected network, all possible cause-and-effect linkages between nodes are described. Through a process of pruning, the structure is simplified to essential links, resulting in an enormous reduction of complexity. This approach is used to diagnose programming errors and to anticipate military trouble spots.

Descriptive Analyses

Most descriptive analyses were initially concerned with discrepancies between normative rules (e.g., EV) and actual decision behavior. In 1954, Ward Edwards modified EV by introducing subjective probabilities and psychological utilities to produce Subjectively Expected Utility (SEU). This model has become the starting point for descriptions of risky decision behavior and has been used for making lending and family planning decisions.

Social Judgment Theory

Based on the "lens model" concept proposed by Egon Brunswik, Kenneth Hammond developed a comprehensive perspective on judgment and decision making. By adapting multiple regression routines, this approach combines elements of normative and descriptive analyses. Central is the distinction between analytic and intuitive modes of cognition. This approach has been used to describe decisions by highway engineers and medical doctors.

Information Integration Theory (IIT)

Analyses of psychological rules used to combine information from multiple sources reveal that people often average inputs. Norman Anderson has shown that an averaging rule is more descriptive than the adding rule assumed in normative models. Through functional measurement procedures, IIT leads to simultaneous evaluation of processing strategies and psychological values. This approach has been applied to marketing decisions and marital choices.

Heuristics and Biases

Amos Tversky and Daniel Kahneman argued that decisions are made using psychological shortcuts or "heuristics." For instance, "representativeness" means probability estimates are based on the degree of similarity of an event to an underlying source; greater similarity implies more accurate estimates. Heuristics lead to "biases" since relevant information, for example, base rate, is often ignored. This approach has been used to explain suboptimal decisions in management and accounting.

Fast and Frugal Heuristics

Simon developed "bounded rationality" to deal with two interlocking components: limitations of the human mind, and structure of the environment. Gerd Gigerenzer extended these ideas to incorporate "fast and frugal" heuristics that take advantage of environmental constraints. Such heuristics have been found to lead to efficient decisions in medicine and forecasting.

Naturalistic Decision Making (NDM)

Naturalistic decision making was developed by Gary Klein to account for decision making by experts in time-sensitive environments. In fire fighting, for instance, there is no time to make normative choices between options. Instead, experts follow a "recognition-primed decision making" strat-

egy—they seek a single course of action based on experience. The NDM perspective has been applied to decisions by military commanders and medical doctors.

Expert Decision Making

Behind advances in decision research has been the need for psychologists to help professionals make better choices. For instance, considerable effort was extended to understand how clinical psychologists make decisions. Although analyses often reveal that experts are biased decision makers, James Shanteau studied domains in which surprisingly good decisions occur. For example, air traffic controllers and agricultural judges generally make accurate decisions.

Conclusions

Despite the differences between normative and descriptive approaches, there have been many successful applications of behavioral decision theory in management. In large part, the successes reflect Ben Franklin's original insight into problem decomposition: Decision making is almost always improved by breaking a problem into parts, working on the parts separately, and then combining them to make a final decision.

MAO INHIBITORS

The MAO inhibitors have important historical, heuristic, and clinical value. Their name is derived from their primary pharmacological action: the inhibition of the activity of the enzyme monoamine oxidase (MAO), which is responsible for the metabolic degradation within neurons of several key monoamine neurotransmitters, including serotonin, norepinephrine, epinephrine, and dopamine.

The MAO inhibitors are among the very first compounds shown to be effective antidepressants. Serendipity played an important role in the discovery of their antidepressant properties. In the 1950s, intensive efforts were launched to develop antibiotic treatments for tuberculosis (TB). An early report of the clinical properties of one of these compounds, iproniazid, described its mood-elevating properties when given to TB patients (Bloch, Doonief, Buchberg, & Spellman, 1954). This fortuitous observation was soon confirmed in controlled trials (Kline, 1984). Several years later, the mechanism of antidepressant activity was found to involve the inhibition of the activity of MAO enzymes (Zeller, 1963). Unfortunately, iproniazid was soon associated with significant liver toxicity, and its use as an antidepressant was discontinued. However, several other compounds with MAO inhibitory activity were then shown to possess antidepressant efficacy.

Shortly after the widespread introduction of the MAO inhibitors into clinical practice, reports emerged regarding severe, at times fatal, hypertensive crises in some patients. Blackwell and colleagues (1967) demonstrated that these reactions were due to the hypertensive effects of tyramine and related compounds in certain foods and beverages. Tyramine can provoke a dramatic elevation in blood pressure, but monoamine oxidase in the gut wall usually breaks it down before it can be absorbed into the body. When the MAO inhibitors block this activity, sudden increases in blood pressure can occur when patients ingest foods that are rich in tyramine. Once this physiological basis for these reactions was recognized, dietary guidelines were developed to allow for the safe use of the MAO inhibitors.

In addition to foods that possess high tyramine content, several medications with sympathomimetic properties are contraindicated for patients receiving MAO inhibitors (see Table 1). These restrictions, and the fear of potentially life-threatening reactions, have substantially diminished the use of these medications, which have now largely been supplanted by the new generation of antidepressants, including the serotonin selective reuptake inhibitors (SSRIs).

The discovery that clinical depression could be successfully treated with the MAO inhibitors had a profound effect on both the practice of clinical psychiatry and on neuroscience research. Coupled with the nearly concurrent discovery of other effective antidepressant (i.e., the tricyclics) and antipsychotic pharmacotherapies, the MAO inhibitors helped to launch the revolution of modern clinical psychopharmacology. Psychiatrists began to incorporate biological therapies into treatment approaches that previously had been dominated by psychodynamic psychotherapy. Also, the relative specificity of action of these medications (i.e., their effectiveness in treating major depression, but not adjustment disorders or normal bereavement) ultimately led to greater emphasis on reliable and valid diagnostic criteria. In the neurosciences, these medications fo-

Table 1. Partial Listing of Food and Medication Restrictions for MAOIs

Foods	Medications
Cheese (except cream cheese)	Tricyclic antidepressants
Overripe fruit (especially banana peels)	Serotonin selective reuptake inhibitors
Fava beans	Meperidine
Sausages and preserved meats	Buspirone
Pickled fish and vegetables	Sympathomimetics (e.g., l-dopa, pseudoephedrine)
Chicken and beef liver	
Red wines, sherry, liquors	
Monosodium glutamate	

Note: This is a partial, representative listing. Patients receiving treatment with an MAO inhibitor should check with their physician for a comprehensive list of prohibited foods and medications.

cused attention on the potential role of the biogenic amine neurotransmitters in the pathophysiology of depression. By blocking the intraneuronal degradation of norepinephrine, serotonin, and dopamine, the MAO inhibitors led to the accumulation of these neurotransmitters and eventually to the release of larger quantities into the synapse, thereby enhancing neurotransmission. These observations of the pharmacological actions of the MAO inhibitors, coupled with their clinical efficacy, formed the basis of several theories postulating that a functional deficit in one or more of these neurotransmitters was responsible for the development of clinical depression. More recently, it has been suggested that the clinical response to the MAO inhibitors may be linked to secondary adaptive changes in various neurotransmitter receptors, and thus their mechanism of action, and the pathophysiology of depression, remain unclear.

There are two types of monoamine oxidase in the human central nervous system and in some peripheral organs. The main substrates for MAO-A activity are the neurotransmitters dopamine, norepinephrine, epinephrine, and serotonin, while dopamine, phenylethylamine, phenylethanolamine, tyramine, and benzylamine are the main substrates for MAO-B. The classic MAO inhibitors (phenelzine, isocarboxazide, and tranylcypromine) irreversibly affect both MAO-A and MAO-B. Newer agents target one of the specific forms of MAO (e.g., selegiline is an MAO-B specific inhibitor) and/or have reversible effects (e.g., moclobemide is a reversible inhibitor of MAO-A).

The primary use of the MAO inhibitors is in the treatment of depression. Several studies have suggested that these medications are especially effective in the treatment of "atypical depression," where the usual physical signs and symptoms of depression are reversed (i.e., hypersomnia rather than insomnia; increased appetite with weight gain rather than decreased appetite with weight loss) (Golden & Nicholas, 2002). There is also substantial research documenting the efficacy of MAO inhibitors in the treatment of panic disorder (Lydiard et al., 1989), although the SSRI's and high potency benzodiazepine derivatives are more widely used. Limited controlled trials have also supported the use of these medications in the treatment of social phobia and posttraumatic stress disorder (Kosten, Frank, Dan, McDougle, & Giller, 1991; Versiani et al., 1992).

Side effects are often more frequent and more severe with MAOIs than with newer antidepressants. The most frequent side effects include orthostatic hypotension, insomnia, dizziness, constipation, blurred vision, and weakness (Krishnan, 1998). Liver damage may occur in rare instances. These side effects, coupled with the concern regarding dietary and medication restrictions and the availability of the new generation of antidepressants, have led to considerable decrease in the use of the MAO inhibitors. However, they are still utilized by many clinicians in the treatment of refractory cases of depression. In the future, the availability of more specific and reversible forms of MAO inhibitors may stimulate their resurgence in clinical practice.

MARIJUANA

Marijuana smoking remains the most prevalent form of illicit drug use in the United States, Canada, Australia, New Zealand, and some European countries. Cannabis is the generic name for the psychoactive substance(s) derived from the plants *Cannabis sativa* or *indica.* Marijuana (a mixture of flowering tops, leaves, and stems of the dried plant) and hashish (extracted resin from the flowering tops) are the most common forms of cannabis smoked to obtain psychoactive effects. Scientists have identified Δ^9-tetrahydrocannabinol (THC) as the predominant substance in marijuana that produces the subjective "high" associated with smoking the plant.

Marijuana was used in the Western Hemisphere both medically and recreationally as early as the eighteenth century. The Marijuana Tax Act of 1937 prohibited the recreational use of marijuana in the United States. Little scientific investigation was directed toward marijuana until the 1960s and 1970s, when marijuana use increased in Western cultures.

Marijuana use in the United States and other countries continues to provoke controversy. Pro-marijuana supporters argue that cannabis has many positive effects, has only minor adverse consequences, is less harmful than other legalized drugs such as alcohol, and has important medicinal uses. Others point to evidence of the adverse effects of misuse and abuse of marijuana, its addictive potential, its possible link to the use of more harmful drugs such as cocaine and heroin, and the lack of evidence for its efficacy and the availability of alternative medicines for treating specific medical conditions. Conflicting and inconclusive scientific findings have contributed to general misperceptions and confusion regarding marijuana.

Epidemiology

In the United States, conservative estimates from the National Household Survey on Drug Abuse indicate that more than 9.3% of the general population over the age of 12 smoked marijuana during the previous year (over 11 million people), and approximately 20% of these smoked almost daily. Approximately, 13% of those who used marijuana in the previous year met the criteria for marijuana dependence or abuse. Dependence indicates that an individual experiences a cluster of cognitive, behavioral, or physiological symptoms associated with substance use, yet continues to use the substance regularly. Lifetime prevalence rates of marijuana dependence (4 to 5%) in the general population are higher than for any other illicit substance, which is clearly due to the greater overall prevalence of marijuana use. The conditional dependence rate for marijuana, or the risk of developing dependence among those who have ever used marijuana, is substantial, albeit lower than for most other drugs of abuse (9% for marijuana, 15% for alcohol, 17% for cocaine, 23% for heroin, and 32% for tobacco).

Marijuana-Related Problems

The lay and scientific communities have questioned both the addictive potential and the harm that may be associated with marijuana use or abuse. However, recent research indicates that misuse of marijuana can have significant psychosocial and perhaps adverse medical consequences. Acute marijuana use typically produces a mild euphoric state that affects sensory awareness, perception of time, appetite, mood, short-term memory, concentration, attention, motor coordination, blood pressure, and heart rate. These effects are dose dependent and vary greatly across individuals. Such effects are typically not as debilitating as those observed with other substances of abuse (e.g., alcohol, narcotics), but nonetheless can increase the risk of accidents and mistakes when performing physical or mental activities.

The types of problems associated with regular marijuana use have also been well documented. Heavy use has been linked to impairment in memory, concentration, motivation, health, interpersonal relationships, employment, and school performance, as well as lower participation in conventional roles of adulthood, history of psychiatric symptoms and hospitalizations, and participation in deviant activities. These problems appear related to frequency and duration of use. Regarding health issues, chronic use clearly increases the risk of respiratory problems (e.g., bronchitis). Of note, marijuana smoke has more carcinogens than tobacco smoke, yet direct links to lung cancer have not yet been observed. Marijuana impacts many other physical systems (e.g., cardiovascular, reproductive, endocrine, immunological, neurobiological). However, the clinical significance of effects across these systems is generally not considered robust, although much more research is needed to provide definitive information.

Marijuana Dependence

As noted above, the majority of those who try and use marijuana do not become dependent or develop significant problems. But as with other substances of abuse, a significant subset of users does develop a dependence syndrome with consequences that are similar to those associated with other types of drug dependence. For many years, the scientific community debated whether marijuana use could produce dependence. The past 10 to 15 years of basic and clinical research have produced strong evidence that marijuana use can and does produce dependence.

Basic research has identified a neurobiological system specific to the actions of marijuana (cannabinoids). At least two cannabinoid receptors (CB1, CB2) and an endogenous cannabinoid (anandamide) have been identified. The syn-

thesis of cannabinoid antagonists (substances that can block the receptor site and hence the actions of marijuana) has facilitated experiments demonstrating that this brain system works much like neurobiological systems specific to other drugs of abuse (e.g., the endogenous opioid system). Moreover, human and nonhuman studies have demonstrated that a withdrawal syndrome can follow discontinuation of chronic use of marijuana or other cannabinoid-like substances, and that this syndrome has many similarities to other substance withdrawal syndromes. Such withdrawal appears relatively common among heavy marijuana users.

Clinical research indicates that many marijuana users willingly seek treatment for problems related to marijuana abuse. The majority of individuals who seek such treatment meet diagnostic criteria for marijuana dependence. These individuals exhibit substantial psychosocial impairment and psychiatric distress, report multiple adverse consequences and repeated unsuccessful attempts to stop using, and perceive themselves as unable to quit. Marijuana abusers do not typically experience the acute crises or severe consequences that many times drive alcohol-, cocaine-, or heroin-dependent individuals into treatment; however, they show impairment that warrants clinical intervention.

Treatment for Marijuana Abuse or Dependence

Treatment seeking for marijuana abuse is increasing. A more than two-fold increase was observed during the 1990s, such that the number of people seeking treatment for marijuana abuse now approximates the numbers seeking treatment for cocaine and heroin. Clinical trials evaluating treatments for marijuana dependence suggest that this disorder, like other substance dependence disorders, is responsive to intervention, yet the majority of patients have much difficulty achieving and maintaining abstinence. The types of treatment approaches with demonstrated efficacy for other substance dependence disorders (e.g., cognitive-behavioral, coping skills, contingency management, motivational enhancement) also appear effective with marijuana dependence. Interestingly, the response to treatment and relapse rates observed among marijuana-dependent outpatients also appear similar to those observed with other substances of abuse, suggesting that marijuana dependence is not easily treated.

Summary

Much remains unknown about the effects of marijuana on human psychological and physical health. Nonetheless, studies have provided strong evidence that marijuana use can produce multiple adverse effects and that many people experience problems related to marijuana use. The demonstration of causal relationships between marijuana and some of these effects has proven difficult, and the magnitude of risk and functional significance of some effects remains elusive. As with other abused substances, many individuals use marijuana without significant consequence, but others misuse, abuse, or become dependent. Dependence on marijuana develops in much the same way as with other drugs, although in general the associated consequences appear less severe than those associated with alcohol, heroin, or cocaine dependence.

MARITAL DISCORD

The large volume of research on marital discord and the related constructs of marital conflict and marital dissatisfaction attest to the perceived importance of understanding the problems that sometimes arise in marriage. Of the various terms used in this area of inquiry, “marital satisfaction” is the best defined, referring to an evaluation of the relationship or the partner. Because of their clarity and brevity, measures of marital satisfaction play a prominent role in all areas of marital research. “Marital conflict” is a somewhat broader term than “marital satisfaction” and is used to refer to spousal perceptions, emotions, anticipations, and behavior in relation to some disagreement or area of differing interests. However, marital conflict is not inherently negative and may or may not be associated with marital dissatisfaction. In some cases marital conflict may set the stage for increases in relationship satisfaction, while in others it may be the harbinger of deterioration in the relationship. For this reason, the study of marital conflict is often considered distinct from the study of marital satisfaction, and researchers in this area place considerable importance on direct observation of marital interaction.

“Marital discord” is also a relatively broad term, referring to a state of marital dissatisfaction in conjunction with any of a number of problems that may beset couples and lead to long-standing marital conflict, loss of marital commitment, feelings of estrangement within marriage, or marital dissolution. Because the construct combines a variety of disparate features, measures of marital discord tend to be collections of heterogeneous items. The most comprehensive self-report instrument of marital discord is called the Marital Satisfaction Inventory. This inventory solves the problem of heterogeneous content by assessing each content area using a separate scale. Its primary disadvantage is its overall length of 150 items. Maintaining the distinctions between different terms used in the area has become increasingly important as research in the area of marital discord has developed. Of particular importance is the distinction between marital dissatisfaction and marital conflict, as these two constructs may often diverge in their implications.

On the other hand, measures of marital dissatisfaction and measures of marital discord are often highly correlated and the two terms are sometimes used interchangeably.

Inquiry into the causes, consequences, and correlates of marital discord is driven, in part, by the perceived importance of better understanding the effect of marital discord on numerous processes related to personal and family adjustment. Supporting this perception, much recent research suggests that marital discord and the related constructs of marital dissatisfaction and marital conflict play an important role in individual and family well-being. For example, marital dissatisfaction commonly co-occurs with depression, eating disorders, and some types of alcoholism, as well as physical and psychological abuse of partners. In addition, marital discord and marital dissolution co-vary with problems of delinquency and may presage children's later problems with intimate communication. Similarly, marital discord is associated with poorer health and with specific physical illnesses such as cancer, cardiac disease, and chronic pain. Marital interaction studies suggest possible mechanisms that may account for these links, showing, for example, that hostile behaviors during conflict relate to alterations in immunological, endocrine, and cardiovascular functioning. Better understanding of marital discord therefore offers the potential for more effective treatment of certain types of individual psychopathology and family difficulty and offers hope for better managing their sequelae. In addition, increased understanding of marital discord may also prove useful in developing better health maintenance strategies and in managing chronic health problems.

Inquiry regarding marital discord is also fueled by the perceived importance of developing harmonious marital relationships as an end in itself. Better understanding of marital discord is sought as a way to guide those attempting to develop interventions to relieve marital discord or those developing programs to prevent marital distress and divorce. That is, understanding marital discord is potentially important because enhancing marital satisfaction and alleviating marital discord are desirable goals in their own right.

As these considerations suggest, there is good reason for continuing research on the topic of marital therapy and developing prevention programs designed to prevent a decline in marital satisfaction and the development of marital discord. Because of the need to control for various extraneous effects, randomized clinical trials of various marital therapy programs have been conducted. The results of these trials indicate that substantial benefit may be obtained from several types of marital therapy, including behavioral marital therapy, emotion-focused marital therapy, insight-oriented marital therapy, and cognitive-behavioral marital therapy. Similarly, promising results have been obtained for divorce prevention programs. However, because of the difficulty in conducting randomized clinical trials on preventative intervention and the difficulty in reaching couples at greatest risk for developing marital discord and divorcing, many questions about the utility of preventative programs remain unanswered. Further, despite advances in treatment and prevention efforts, fewer than half of discordant couples receiving marital therapy remain maritally satisfied at long term follow-up. Likewise, the majority of couples in need of prevention services do not seek them out. Accordingly, there is considerable room for progress in the development of marital interventions and divorce prevention programs.

MARRIAGE COUNSELING

It has been estimated that within the United States, most people (over 90%) will marry by the end of their lives, and that nearly 50% of recent marriages may end in divorce (Kreider & Fields, 2001). The fact that so many couples have problems in their relationships supports the importance of developing effective approaches to preventing and treating relationship difficulties.

Research has shown that marriage counseling is an effective form of treatment for marital discord. Results from studies comparing treatment groups to no treatment control groups have consistently found that counseling increases relationship satisfaction, which is the most commonly evaluated outcome measure. One way to quantify the impact of treatment is through effect size statistics, which provide information regarding the degree to which counseling is effective. Shadish et al. (1993) reported a mean effect size of .71 across 16 outcome studies that evaluated the effect of marriage counseling on global relationship satisfaction. An effect size of .71 translates into a treatment success rate of approximately 67% for treated couples versus 34% for untreated control couples.

In addition to improving relationship satisfaction, researchers have evaluated marriage counseling as a treat-

ment for mental and physical health problems. Providing couple therapy for mental and physical health problems is based on research findings indicating that when couples have problems in their relationships, there are often co-occurring emotional and behavioral problems (e.g., Whisman, 1999). To date, marriage counseling has been shown to be effective in treating mood disorders, anxiety disorders, alcohol use disorders, and sexual disorders (Baucom, Shoham, Mueser, Daiuto, & Stickle, 1998). Thus, there is evidence that marriage counseling is effective in treating problems traditionally viewed as "individual" problems, as well as treating relationship difficulties.

There are several major theoretical approaches to marriage counseling. One of the most thoroughly researched approaches is behavioral marriage counseling (Jacobson & Margolin, 1979), which focuses on increasing pleasing exchanges (i.e., caring behaviors) between partners, as well as improving communication and problem-solving skills. A related approach focuses not only on modifying behavior, but also on modifying partners' interpretation of that behavior. In this approach, labeled cognitive-behavioral marriage counseling (Epstein & Baucom, 2002), the goal is to teach couples ways of identifying and modifying cognitions that are associated with marital problems. A second treatment approach is emotion-focused marriage counseling, which conceptualizes relationship problems in terms of the disruption of attachment bonds (Greenberg & Johnson, 1988). This approach targets problems of adult attachment insecurity by modifying couples' interaction patterns and the emotional responses that evoke and are evoked by these interactions. A third approach is insight-oriented marriage counseling (Snyder & Wills, 1989), which focuses on helping couples become aware of interaction patterns, relationship cognitions, and developmental issues that are either totally or partially beyond conscious awareness.

In addition to developing different theoretical approaches to working with couples, there has been a recent movement towards developing integrating approaches that cut across treatment modalities. For example, Jacobson and Christensen (1996) have developed an approach to marriage counseling that promotes acceptance between partners, as well as change strategies similar to those emphasized in behavioral marriage counseling. To date, there is little evidence to suggest that these different approaches yield different outcomes in terms of relationship satisfaction. Furthermore, there are few empirically-based guidelines to help match couples with the type of treatment that would be most beneficial to them.

Another important development in marriage counseling has occurred in the area of prevention of relationship problems. Research has shown that cognitive-behavioral approaches to premarital counseling—which typically involve lectures, group or couple discussions, and exercises involving practice of relationship skills—are effective in improving satisfaction and reducing divorce rates. Hahlweg and Markman (1988) reported a mean effect size of .79 across seven outcome studies that evaluated cognitive-behavioral prevention programs, which translates into a treatment success rate of approximately 69% for treated couples versus 32% for untreated control couples.

Although there have been a number of advances in the development and evaluation of marriage counseling, there are several understudied areas needing additional research (Christensen & Heavey, 1999). For example, there is a need for research on the impact of marriage counseling for different types of couples, including nontraditional couples (e.g., same-sex couples, cohabiting couples), older couples, and members of ethnic minority groups. Furthermore, there is a need for research evaluating longer-term outcome following marriage and premarital counseling, and research evaluating the impact of marriage counseling on other types of outcomes (e.g., children, individual functioning).

MASOCHISM

Sadomasochism is common among sexual deviations, more prevalent in men than in women. Women who perform sadistic acts for money or to please men are not necessarily sexually excited. Young women who cut their arms with razors do so to obtain relief from psychological distress, not for sexual satisfaction. The literature of this subculture is among the best selling in bookshops and newsagents. It has long exercised a considerable influence upon fashion and the visual images and story content of science fiction. Most animated cartoons and slapstick comedies contain sequences in which extremely painful happenings are presented for enjoyment.

Some sexologists, among them Schrenck-Notzing, preferred the term "algolagnia," emphasizing pleasure in pain, whereas Krafft-Ebing's terms, sadism and masochism include pleasure in humiliation, dominance, and subjection. Sadism takes its name from the writings and exploits of Donatien Alphonse François, Marquis de Sade, found to have been one of the nine prisoners held in the Bastille when it was stormed in 1789. It denotes a condition in which erotic pleasure is derived from inflicting pain or humiliation. The more puzzling condition of masochism, in which erotic pleasure is obtained from being hurt, restrained, or humiliated, is so named after the writings and activities roughly a century later of the Chevalier Leopold von Sacher-Masoch. The coupling of the two names in sadomasochism is important as the two conditions are usually present, albeit with one or the other predominating, in one and the same individual. This individual may also display other deviant interests, for instance in fetishism or transvestism. Freud pointed out that the sexuality of infancy is "polymorphously perverse," and some masochists actually visit "Adult Baby" clubs.

Many of those engaging in sadomasochistic ritual will state that this interaction is all about control and is dictated by the masochist. Their explanations are, however, seldom adequate to the impenetrability of the phenomenon they are addressing. A somewhat simplistic account is given in a medical encyclopedia: a glandular insufficiency, especially of the gonads and adrenals, demanding the stimulation of pain before the subject is able to react to sexual stimuli. Trying to explain masochism without Freud would be like trying to explain gravity without Newton. In 1924, Freud wrote in *The Economic Problem of Masochism:* "The existence of a masochistic trend in the instinctual life of human beings may justly be described as mysterious from the economic point of view. For if mental processes are governed by the pleasure principle in such a way that their first aim is the avoidance of unpleasure and the obtaining of pleasure, masochism is incomprehensible. If pain and unpleasure can be not simply warnings but actually aims, the pleasure principle is paralysed—it is as though the watchman over our mental life were put out of action by a drug. Thus masochism appears to us in the light of a great danger, which is in no way true of its counterpart, sadism. We are tempted to call the pleasure principle the watchman over our life rather than merely over our mental life." Few psychologists would wish to dispute the primacy of this principle. The whole edifice of behaviorism is built upon it. The fact that masochism is sometimes literally a danger to life itself is attested to by the deaths following certain rituals of "bondage" and hypoxyphilia (sexual arousal by oxygen deprivation)—about 50 a year in the United States according to coroners' records of 30 years ago and almost certainly more numerous today.

As Freud pointed out, a child will repeat an unpleasant experience in its play in order to gain control of it. The masochist, who has never grown up, recreates not once, but many times, the situation he fears in order that he shall not, in retrospect, be its hapless victim but, indeed, its instigator. This is not likely to benefit those in his path! It is not difficult to recognize that his "mishaps" are provocations because he will never apologize or express regret as he would if they were truly inadvertent.

Mervin Glasser has, out of his extensive clinical involvement with sadomasochism at the Portman Clinic, London, put his finger on an important and frequently encountered etiological factor: incomplete individuation. He explains it in terms of a "core complex": a pervasive longing for closeness to another person, amounting to a "merging," which invariably awakens the fear of a permanent loss of self as soon as closeness is offered. The flight to a safe distance brings a sense of isolation and, in a vicious circle, the return of longing for union. Aggression, aroused by this threat of obliteration, cannot be directed towards the potentially engulfing person (originally the mother)—it may, however, be focused on the self, and it may be sexualized and the relationship preserved in sadomasochistic mode. Many masochists lack a sense of identity apart from that of their family or their childhood background. Any struggle for autonomy which may have started, perhaps with adolescence, has failed. Some not only have an obvious reluctance to achieve satisfaction in conventional sexual intercourse with a partner, which might be a reluctance due to a sense of guilt, but they even fear such a loss of control as the culmination of a punishment ritual. They would rather masturbate alone afterwards. This confirms Glasser's interpretation that masochists need to regulate their movement toward or away from a partner, ensuring that they do not lose control of the situation in the partner's presence and expose themselves to the danger of being engulfed.

Some masochists describe sexually colored incidents in their childhood involving rubber or plastic articles, and attribute to these incidents their lifelong interest in rubber or shiny plastic as sexual stimuli. Fetishes may bear some resemblance to the "transitional objects" postulated by Donald W. Winnicott. John Bowlby preferred the term *substitute objects,* explaining that inanimate objects, such as teddy bears, have attachment behavior directed toward them because the attachment figure is unavailable. Like the attachment figure, they are sought particularly when a

child is tired or sick or upset. One might perhaps add also that when a child is bored, the physical properties of the substitute object itself might become salient. In a final step, they might become sexual stimuli through masturbation. In pursuit of their fetish, some adolescents and adults find themselves confronted with pornographic literature which leads them into the SM scene. What they at first encounter in sex shops as a contiguous interest gradually extends its fascination and becomes central to their deviance. As to the fetishistic paraphernalia on sale in sex shops, a mask or uniform may serve to conceal the ordinary and create a new and powerful identity.

In cases of prolonged illness or severe injury in childhood, the endogenous opioids produced as a biological response to these situations may create an addiction to pain and stress, for they have been reported as many times more addictive than morphine and other exogenous opiates. They were reported definitively by Kosterlitz and Hughes in 1975 in the journal *Nature.* The interest, the controversy and the literature generated by these neuromodulators have, in fact, been immense. The receptors to which they bind have been found in many parts of the human body, but chiefly in pain pathways and limbic regions of the brain. They have been implicated in strenuous physical exercise—an "endorphin rush" has now become part of common parlance. What is firmly established, however, and of prime significance, is that they are, like morphine, both pain-killing and addictive. They are actually produced by pain or stress, and they relieve it by reducing neural excitability. Pleasure, often referred to in the literature as "the reward factor," follows. The practising masochist is a person for whom "normal" sexual release by means of the genitals is at best problematic. Often, the anus and buttocks are more erotogenic than the genitals. If one looks into the childhood of a masochist, one frequently finds an accident or illness involving intense, protracted, physical pain, or repeated beatings, or a situation causing severe, prolonged stress. These events, usually only the beginning of a series, have not only psychological but also physiological consequences, one of these being the release of endogenous opioids. As painful event succeeds event, what happened at first by ill chance is later engineered. He is addictively seeking pain and in some cases he even knows it and explicitly states it.

Thus the etiology of masochism may be predominantly physical through injury, illness, or stress; predominantly psychological through maternal rejection, parental divorce, or death for which the masochist attributes guilt to himself; or a combination of both through corporal punishment, hospitalization, persecution by or envious hatred of siblings, a puritanical home atmosphere where sexual relations are considered sinful or disgusting, or a bullied and miserable school life. Where sadomasochism finds no outlet in sexual activity it is likely to spill over from sexuality into the personality. Particularly in women, martyrdom may be a way of transferring guilt to others. As the neurologist and psychiatrist Kurt Goldstein noted, the healthy personality is characterized by flexible functioning, the damaged personality is rigid; healthy functioning is planned and organized, disturbed functioning is mechanical; the healthy person can delay and anticipate the future, the disturbed personality is bound by the past and the immediate present.

Theodor Reik's depiction of masochism is arguably the most accurate after Freud's. He identifies its quintessential characteristics as a predilection for fantasy, the seeking of suspense, and what he calls the demonstrative feature. (To these one might add rigidity, infantilism, hypocrisy, and passivity.) At the end of *Masochism in Modern Man,* Reik seeks the common denominator in the various manifestations of masochism—sexual deviance and personality disorder alike—and finds it in the formula "victory through defeat." This is indeed the kernel of masochism and there is no doubt that the highly specific victory is total. The man whose aim is to be defeated has achieved a desperate invulnerability. The masochist who operates primarily through deviant sexual practices, the "supersensualist," as Sacher-Masoch styled himself, defiantly obtains gratification in spite of every obstacle, every delay, every embargo. The masochist who, in each situation life presents, systematically ruins his chances of happiness and success, is locked within a vicious circle of guilt, requiring punishment, punishment affording masochistic satisfaction, thus begetting more guilt, requiring more punishment.

Sadomasochism has been described by the psychiatrist Otto Kernberg as a continuum—a spectrum would be another metaphor, with feckless theatrical games at one end and sadistic serial killings at the other. The danger comes when preoccupation with immediate physical pleasure takes over, when other human beings are seen only as insensate means of sexual gratification, and this is indissolubly linked with domination. That at the other end of the spectrum, everyday human relations are shot through with covert sadomasochism is, sadly, as irrefutable as saying that Homo sapiens is a dangerous species.

Of course, masochists have other qualities besides deviance and sometimes, where fantasy is creative as opposed to emprisoning, considerable talents or skills, as in the cases of Gesualdo, Mussorgsky, Bartok, Rousseau, Dostoevsky, Swinburne, C. S. Lewis, T. E. Lawrence, and Yukio Mishima, to mention but a few.

University College, London

MASTURBATION

Masturbation is the term used to signify any type of autoerotic stimulation. Both males and females indulge in stimulation of the genitals for sexual gratification. The term is

also applied to an infant's manipulation of the genitals, a common exploratory behavior in the early years. During adolescence, masturbation becomes one of the main sexual outlets, and remains so for many adults. Michael, Gagnon, Laumann, and Kolata (1994) found that among Americans, 60% of men and 40% of women report that they have masturbated during the past year. Twenty-five percent of men and 10% of women say they masturbate at least once a week. Estimates vary, depending on the studies cited and the specific approaches used in collecting the data.

Of all the areas of sexual behavior, masturbation appears to be subject to the widest variation in reported frequency, owing no doubt to the privacy of this behavior and the shame that has traditionally surrounded it. While in earlier historical periods masturbation was considered a sign of depravity or sinfulness, it is more generally accepted today as a common practice among adolescents and adults, both male and female.

MEDICAL MODEL OF PSYCHOTHERAPY

The medical model has been applied to several areas, including physical illness, psychiatric illness, and psychotherapy. Although several features distinguish the medical model of psychotherapy from those of physical and psychiatric illness, the models also share similarities. A discussion of applications of the medical model to physical and psychiatric illness will help to define and delineate the medical model of psychotherapy.

The Medical Model of Physical and Psychiatric Illness

The medical model of physical illness rests on the assumption that the etiology of a disease can ultimately be traced to the disruption of internal physiological processes. Further, it is often posited that this disruption is caused by specific pathogens such as viruses, bacteria, toxins, genetic abnormalities, or cellular dysfunction. To relieve symptoms of an illness and return the patient to a state of health, the medical model requires that the practitioner correctly diagnose the disorder, identify the underlying pathology, and provide an intervention that removes, inactivates, or reverses the action of the internal pathogen.

Applied to psychiatric illness, the medical model presupposes that a patient's report of disturbed mood, problematic thoughts, and/or aberrant behavior is caused by the disruption of internal physiological processes such as neurochemical abnormalities or central nervous system damage. Operating from this perspective, a practitioner will attempt to treat the underlying pathology by prescribing or supporting the use of medications, surgical interventions, or electroshock therapy.

The Medical Model of Psychotherapy

The medical model of psychotherapy is based on a set of assumptions similar to those described above. That is, supporters of the medical model of psychotherapy argue that the primary causes of behavior problems may be traced to the dysregulation of internal processes. Unlike the medical model of illness, however, the medical model of psychotherapy replaces biological pathogens with what may be described as *intrapsychic pathogens*—dysfunctional internal psychological processes that give rise to problematic behavior. Many examples of intrapsychic pathogens have been reported in the psychoanalytic and psychodynamic literature, including unconscious conflicts, poor ego development, psychosexual fixations, unconscious defenses, childhood traumas, and impaired object relations (e.g., Fenichel, 1945; Freud, 1933/1964; London, 1986; Luborsky, 1984; Luborsky, Barber, & Crits-Christoph, 1990). Because practitioners endorsing the medical model of psychotherapy view intrapsychic factors as the primary cause of behavior problems, assessment and treatment procedures target presumed internal psychological processes as opposed to external (e.g., situational) processes.

Evaluation of the Medical Model of Psychotherapy

Several criticisms of the medical model of psychotherapy have been put forth by authors who endorse a scientifically-based cognitive-behavioral approach to assessment and therapy (e.g., Barrios, 1988; Hawkins, 1986; Haynes & O'Brien, 2000). First, because internal, unobservable, and hence, unmeasurable intrapsychic processes are cited as the primary cause of behavior, critics argue that the medical model of psychotherapy is more apt to generate nonscientific and untestable explanations of behavior disorders. Second, critics argue that there is very little scientific evidence supporting two critical assumptions underlying the medical model of psychotherapy: (1) that intrapsychic factors are the primary cause of disordered behavior, and (2) that treatments that primarily target intrapsychic factors (e.g., psychodynamic and psychoanalytic approaches) yield better client outcomes relative to interventions that target external factors (e.g., behavioral approaches) or a combination of external and internal factors (e.g., cognitive-behavioral approaches). In fact, several meta-analytic reviews suggest that psychoanalytic and psychodynamic interventions typically produce outcomes that are inferior to behavioral and cognitive-behavioral interventions (e.g., Pinquart & Soerensen, 2001).

A third criticism relates to patient diagnosis and labeling. Specifically, because the medical model locates the cause of disordered behavior within the individual, practitioners who endorse this view may be more apt to believe that their clients have long-standing and less treatable personality-based problems (Brehm & Smith, 1986). In turn, these practitioners may be unrealistically pessimistic about the possibility for client improvement.

Recent changes in mental health care have also adversely affected the acceptance and use of the medical model of psychotherapy. Specifically, because practitioners are now required to demonstrate more clearly that their treatments yield cost-effective outcomes, scientifically supported behavioral and cognitive-behavioral treatments are increasingly used to treat a wide array of psychological disorders (Chambless & Hollon, 1998; Geraty, 1995). Alternatively, because there are limited scientific data supporting the use of interventions that target intrapsychic factors, techniques based on the medical model of psychotherapy are less frequently used in clinical practice (Altshuler, 1990).

To address declining use and the changing health care environment, the medical model approach to psychotherapy is now expanding to include more scientifically supported procedures and to incorporate interdisciplinary techniques (Gabbard, 1994; Weissman, 1994). Although proponents of the model argue that their approach may be less amenable to traditional research techniques than other approaches, increased empirical validation of the medical model approach to psychotherapy is critical for its survival (Strupp, 2001).

Summary

The medical model approach to psychotherapy, like the medical model of illness, rests on the assumption that problematic behavior arises from the disruption of internal pathogenic processes. As a result, assessment and treatment emphasize the measurement and modification of presumed intrapsychic determinants of behavior. Criticisms of the medical model combined with changes in mental health care have reduced the acceptability of this approach and, as a result, it is less frequently used in clinical settings. Adherents of the medical model are calling for changes that will permit inclusion of scientifically-based assessment and treatment procedures. This broadening of the medical model will be needed if it is to survive as an approach to psychotherapy.

MEMORY DISORDERS

Information learned and events experienced are considered to be more or less permanently stored in memory. To understand memory, an information-processing analogy may be helpful. Information is entered through the senses, operated on, stored, retrieved, and utilized. The operations stage has functions of attaching appropriate cues to infor-

mation, linking related events, setting priority, and selecting information to avoid confusion.

Obviously, efficient retrieval is the objective of any memory system, but achieving it is not always easy. Retrieval can be hampered by lack of *availability.* When too much information is taken in, memory capacity can be exceeded and information is lost. When too much time elapses between instances of retrieval, old memories fade. Retrieval can also be hampered by lack of *accessibility.* Attaching inappropriate priority to information may lead to failure to recall the highest priority information; poor attention and highly similar cues applied to other information can cause confusion and interference during retrieval. Memory loss due to lack of availability and/or accessibility results in the most frequent, nonpathological form of memory disorder: *forgetting.*

Forgetting due to loss of availability of stored information can occur with too little rehearsal or repetition of the information to be remembered, or when recently acquired information receives priority over previously learned information, making the old information no longer available. A common cause of forgetting is confusion or interference from acoustically or semantically similar information.

Amnesia, or the loss of memory, can be either anteriograde or retrograde and is caused by emotional or cortical trauma and by alcohol or barbiturate abuse. Amnesia can be (1) *localized,* so that specific features of the time frame around the trauma fail to be both accessible and available for recall; (2) *selective,* as evidenced in the failure to recall particular events like the death of a loved one, an automobile accident, or war experiences; (3) *generalized,* as evidenced by the inability to recall all one's life events up to and surrounding the time of a traumatic experience; or (4) *continuous,* where there is failure to recall events around the traumatic event and into the present. Generalized and continuous types are much less frequent than localized and selective types.

Memory disorders evidenced during *senility* indicate a clarity in memory for events from the distant past interjected inappropriately into the present. The information recalled is frequently viewed as somewhat trivial by others, but has emotional and situational importance for the person.

Memory disorders are also evidenced by *confabulation* or story telling to fill in for periods of blanking caused by alcohol or substance abuse. Here, substance abuse seems to interfere with the encoding and storage capabilities, so that both availability and accessibility are disrupted for periods that may exceed 48 hours. Similar blanking appears during epileptic episodes and schizophrenic catatonic stupors.

Special cases of memory disorders are evidenced in the intellectually retarded. With them, despite highly rehearsed motor and elemental intellectual exercises, memory is frequently short-term; rarely is it available for the past 24 hours. Other special cases of memory disorders are evidenced by the aphasias. Here, previously learned and frequently used abilities such as reading, speaking, writing, and picture recognition are lost through a neurological disorder that may be precipitated by cortical trauma, stroke, and so on. In such cases, formerly competent readers become *alexic* and lose the ability to read. Others who had had fine motor skills now become *apraxic* and lose the capacity for fine motor movement, and still others who were highly adept socially become *prosopagnostic* and lose the ability to recognize faces.

MEMORY, STRESS, AND PROBLEM SOLVING

Can stress likely affect the efficiency of memory and its mechanisms? Generally, it is agreed that the degree of retaining the completeness of an event will determine how effectively its details are encoded, and how easily the memory can be retrieved. This notion was posited as "depth of processing," but recently has been discussed more often in terms of elaboration (Craik & Lockhart, 1972; Craik & Tulving, 1975).

Mandler (1979) suggested that elaboration illustrates the complexity of interstructural links that are developed in the process of encoding, and that these links provide better access at the time of retrieval. These findings about memory and storage retrieval suggest that the restriction of conscious capacity that occurs as a result of stress could have obvious effects on memory functions. Under conditions of stress we tend to remember fewer things that occur and these less well; thus, events will be less elaborately coded under stress. Anecdotal evidence, at least, supports this hypothesis. Unfortunately, there is little experimental evidence on the effects of stress on complex storage and retrieval processes. Available data tend to be rather dated and are limited to supporting the point that stress (frequently defined as failure) impairs memory. The only extensive set of data concerns the effect of stress on short-term memory, and shows that practically any kind of stress, failure experience, or uncontrollable noise will impair short-term memory retrieval. Since short-term memory, as used in the experimental research literature, is to some extent coextensive with span of attention or consciousness, such a finding is not surprising and adds little to our understanding of more complex processes.

Both lay people and mental health professionals recognize the phenomenon that when under stress, the thought processes involved in problem solving demonstrate a kind of narrowing and stereotyping. Because much of problem solving requires the manipulation in consciousness of alternatives, choices, probable and possible outcomes, consequences, and alternative goals, the internal noise of stress and autonomic nervous arousal should and does interfere with problem solving. Thought processes become narrowed in the sense that only the very obvious alternatives are con-

sidered and no conscious capacity is available to evaluate other alternatives. The restriction on memory elaboration leads to a similar restriction on elaboration that is present during problem solving under stress. Examples of these consequences appear in the discussions of available data on the problems of central and peripheral processing under stress.

Understanding more precisely the impact of stress on memory and problem solving requires experimental research studies dealing with analyses of problem solving processes under stress. How and when does the introduction of stress (however produced or defined) constrain the available alternatives in the conscious state? Which processes are suppressed or removed from consciousness and in what order? Does the stress-induced inability to solve a problem synergistically further stress reactions because of the failure to solve the problem? How is hypothesis sampling affected by stress conditions? Under what circumstances can the focusing that occurs under stress be beneficial, promoting more efficient problem solving? The research potential is great, yet our preoccupation with the unstressed mind has restricted experimental work on these problems.

MENSTRUATION

Menstruation refers to normal vaginal bleeding that is usually monthly. The endometrium (uterus lining) sheds when a woman is not pregnant. The menstrual cycle refers to the time from the menstrual flow until the day before the next bleeding (commonly called a "period") begins. Normal flow lasts for 3–5 days, and the total amount of fluid is about 20–40 ml (four to eight soaked regular tampons or menstrual pads).

Menstruation is a normal biological phenomenon. However, menstruation is viewed negatively in Western culture. This taboo has lessened during the past decades, and varies with gender and age as well as cultural background.

A young woman in North America has her first menstruation (menarche) at about age 12, although between 10 and 14 years is normal. Menstruation continues cyclically for several decades until the final menstrual period at an average age of 51. A woman is menopausal once she has had a year without menstrual flow. The menopause transition (or perimenopause) occurs during the final years of menstruation and lasts about four years from the start of irregular periods. Perimenopause is a time of change with high or variable estrogen levels, ovulation disturbances, and consequent changes in flow, unpredictability of menstrual cycles, and more intense premenstrual experiences.

The menstrual cycle may also describe the cyclic hormonal changes that are orchestrated by coordination of signals from the brain and pituitary with hormones from the ovary. All estrogen produced during a given cycle is made by the cells of one particular *dominant follicle* (larger nest of cells surrounding one egg). This follicle begins to grow during menstrual flow, increasing in size and in the amount of estrogen it makes to the middle of the cycle. As it enlarges it develops a cyst (small sack) of fluid that may normally grow to 2 to 3 cm in size. Next, the cyst ruptures and the egg is extruded—this is called ovulation. Following ovulation, cells that lined the follicle form a new body, called the corpus luteum, that makes progesterone as well as estrogen. If ovulation does not occur, progesterone levels do not rise and the ovary is left containing a cyst.

Although the typical menstrual cycle is 28 days long and ovulation ideally occurs on day 14, there is wide variation in the length of menstrual cycles and the timing of ovulation. A normal menstrual cycle is between 21 and 36 days long. Luteal phase length (the number of days from ovulation until the next flow starts) is also variable. Normal luteal phase lengths are 10–16 days.

An interested woman can detect three events in the menstrual cycle. One is a sustained rise of about 0.22 degrees Celsius in first morning temperature. This rise follows ovulation by about 24 to 48 hours. Progesterone raises the core temperature through its action in the brain. The temperature rise continues until the end of the menstrual cycle. If a woman is pregnant she will usually not have a period and her temperature will remain elevated.

The second event occurs before ovulation and is the response of glands at the cervix (opening of uterus into the vagina) to the increasing estrogen. Estrogen stimulates production of clear, stretchy mucus that resembles egg white—this creates an ideal environment in which sperm can swim into the uterus. After ovulation (because progesterone suppresses the cervical glands' production), the stretchy mucus disappears. If there is no ovulation, stretchy mucus can be detected throughout the cycle.

Finally, near the middle of the cycle a pituitary hormone called *luteinizing hormone* (LH) can be detected using an over-the-counter urine test kit. This test can tell whether a woman is going to ovulate and is used as an aid to fertility.

When ovulation occurs late in a menstrual cycle, this is called short luteal phase. It is defined as fewer than 12 days

between the LH peak and flow or fewer than 10 days between temperature rise and the next menstruation. Short luteal phase cycles are associated with early miscarriages and infertility. In addition, short luteal phases are associated with risks for low bone density (and subsequent osteoporosis). Short luteal phase cycles are common during the first 12 years following menarche and during the menopause transition, but may occur at any time.

Menstrual cycle and ovulation changes are caused by physical or emotional stresses (such as examinations at school, psychological abuse, heavy exercise training, decreased food intake, or being ill). The most subtle of these changes is shortening of the luteal phase length. More intense stress may cause anovulation (lack of ovulation) that may occur in a normal or irregular cycle. Several stressors operating together or young gynecological age (number of years following menarche) may cause oligomenorrhea (cycle lengths longer than 36 days). Absence of menstruation for six months is called amenorrhea.

Emotional stress related to worry about gaining weight (called *cognitive dietary restraint*) in a normal weight woman is associated with short luteal phase cycles and also with higher urinary excretion of the stress hormone cortisol, and with increased risk for osteoporosis.

A woman's physical and emotional experiences fluctuate during her menstrual cycle in concert with hormonal changes. These normal, unremarkable changes are known collectively as *molimina.* Some use this term for all premenstrual changes, but it may be specific for cycles with normal ovulation. Slowly increasing moderate exercise reduces premenstrual symptoms, as does taking supplemental calcium (1200 mg/d).

In the past few decades, the concept of a "premenstrual syndrome" or PMS has arisen. Some women experience a premenstrual exaggeration of the normal ebb and flow of experiences, particularly emotional lability, fluid retention, increased appetite and cravings, and breast tenderness. The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) currently includes a diagnosis of Premenstrual Dysphoric Disorder for premenstrual mood changes. There are many publications in the popular and scientific literature on the topic of PMS, but the science behind this designation and the validity of the underlying concepts remain unclear.

Physiological processes that vary across the menstrual cycle include exercise performance, lung function, and glucose metabolism. Additionally, there have been reports of a number of medical conditions that vary across the menstrual cycle. The classical term for these is "catamenial." Some examples include migraine headaches, asthma, and epileptic seizures. In general, the research in this area has been minimal and most studies are not adequately controlled.

Adequate or high levels of estrogen with too little or no progesterone are associated with flow and cycle disturbances and are common after menarche and in perimenopause. Any flow heavier than 16 soaked regular-sized pads or tampons in one period is abnormal and puts a woman at risk of anemia (low blood count). Menstrual cramps (dysmenorrhea) occur before and during flow especially during the teens and often increase in perimenopause. They can be treated with anti-inflammatory medications such as ibuprofen, taken at the first feeling of pelvic heaviness and repeated as soon as cramps start to recur.

MENTAL IMAGERY

Around the turn of the century, mental images were frequently mentioned in controversies concerning cognitive experiences. Whether images were crucial to thinking became a significant issue of contention among both theoretical and empirical psychologists in Germany at that time. John B. Watson, the father of behaviorism, regarded mental images as nothing more than mere ghosts of sensations and of no functional significance whatsoever. Subsequently, experimental psychologists ignored the existence of images and worked almost exclusively with linguistic and behavioral associations. More recently, however, mental imagery has become one of the most significant issues in cognitive psychology.

Researchers like Hobart Mowrer, Silvan Tomkins, and others paved the way for the "return of the ostracized." For almost three decades, Allan Paivio has been at the forefront of both research and theory relating memory processes to imagery. His research has led to the conclusion that "imagery variables are among the most potent memory factors ever discovered" (Paivio, 1972, p. 253). Paivio has interpreted his results in terms of a dual coding model which contains the underlying assumption that there are two main modes of coding experience: verbal and imaginal. The dual coding hypothesis has generated a great deal of research (Paivio, 1971, 1990).

Current Imagery Research and Theory

Stephen Kosslyn, Allan Paivio, Alan Richardson, Peter Sheehan, Roger Shepard, Jerome Singer, and many others have demonstrated that imagery plays an important role in learning, memory, language, thinking, problem solving, perception, emotion, motivation, creativity, sexual behavior, and numerous other aspects of human behavior. This research has also revealed the functional characteristics that distinguish imagery from verbal symbolic processes. This differentiation has been further supported by neurophysiological and clinical work. The imagery system, because of its concrete and contextual nature, appears more akin to perception.

While interest and research in imagery have mounted, there certainly has been less than complete agreement concerning the nature and function of images. Over the years, in addition to dual-coding models, several other significant theories have been advanced: U. Neisser's percept analogy; D. Hebb's cell assemblies; T. Moran's propositional model; Kossly, Schwartz, and Pinker's array theory; A. Trehub's neural networks; R. Finke's levels of equivalence; R. Shepard's psychophysical complementarity; Z. Pylyshyn's tacit knowledge account; and G. Hinton's structural descriptions (Sheikh, 1983). These theorists fall into two groups: to use Dennet's terms, the "iconophiles, those attributing a special nature to mental imagery representations and giving the reported special nature of images some important theoretical status, and the iconophobes, those who believe that images are mentally represented in the same way as other forms of thought with no special status accorded to some intrinsic 'spatial' or 'pictorial' nature" (Pinker & Kosslyn, 1983, p. 44). In R. Shepard's words (1978, p. 127), "current controversy concerning mental imagery seems to have focused on two closely related questions: (a) Do the mental images that some of us undeniably experience, play a significant functional role in our thinking or are they mere epiphenomenal accompaniments of underlying processes of very different, less pictorial character? and (b) What exactly are mental images or, more specifically, what sort of physical processes underlie them in the brain, and to what extent are these processes, like pictures, isomorphic to the external objects that they represent?" (Also see Shepard & Gooper, 1982.) The long-standing debate between the iconophiles (favoring depictive representation) and the iconophobes (favoring propositional representations) appears to have been resolved in favor of the former (Behrman & Kosslyn, 1995; Kosslyn, 1994).

Whether images represent a direct encoding of perceptual experiences, an artifact of propositional structuring, or a constructive and reconstructive process has not been of any real concern to the majority of clinicians and experimenters. They assume that everyone experiences mental representations of objects and events, and these representations constitute their subject matter. A definition of imagery such as the one by A. Richardson is implicit in most of these approaches: "Mental imagery refers to all those quasi-sensory or quasi-perceptual experiences of which we are self-consciously aware, and which exist for us in the absence of those stimulus conditions that are known to produce their genuine sensory or perceptual counterparts" (Richardson, 1969, p. 2).

Classification of Images

On the basis of twentieth-century investigations, A. Richardson has identified four classes of mental images which may be compared with respect to clarity, vividness, localization, fixedness or stability, completeness of detail, susceptibility to scanning, and degree of likeness to the sensory percept. The identified classes are: (1) afterimages, (2) eidetic images, (3) thought images (or memory images), and (4) imagination images (Richardson, 1969, 1994).

Afterimages closely resemble percepts, having a strong sensory quality. Usually afterimages result from actual perception of a stimulus object; they are representations of the object's form and, positively or negatively, of its hue.

Eidetic images are another form of percept-like images. Two types of eidetic images are reported: those resembling prolonged afterimages occasioned by percepts, and those originating in memory or the general process of imagination. Both types are characterized by clarity and detail. Existing studies accept the prevalence of eidetics among children, but among adults they are thought to be extremely rare.

Thought images tend to be pallid, fragmented, indefinitely localized, and of brief duration. However, they have the potential for extreme vividness and clarity, and conceivably could be cultivated for these qualities.

Imagination images are significantly influenced by motivational states and generally involve concentrated quasi-hypnotic attention along with inhibition of associations. Imagination images include the following relatively distinct forms: hypnagogic images, perceptual isolation images, hallucinogenic drug images, and sleep deprivation images.

Assessment of Mental Imagery

Self-reports or questionnaires traditionally have been the most frequently utilized method of measuring individual difference in imagery ability. These measures have dealt with three aspects of imagery ability: (1) vividness or clarity of the images, (2) imagery types (whether subjects differ as to the modalities in which the clearest images occur), and (3) imagery control (whether some people can manipulate their images at will better than others).

Another group of methods measures the facets of consciousness that reflect experience more directly. Examples of such measures are the thought-sampling method introduced by Eric Klinger, which aims to assess subjects' "current concerns," and the Experiential Analysis Technique of Sheehan, McConkey, and Cross. The main difference between these types of assessment and self-report inventories is that the former draw upon the ongoing stream of consciousness rather than upon retrospective comments on experience. Thus, they may be more valid for assessing the facets of cognition that distinguish current everyday thought (Sheikh, 1983).

Attempts have also been made to infer imaging ability from behavioral performances. The most compelling performance tests are those developed in conjunction with the assessment of eidetic imagery, for example the Random-Dot Stereogram Test.

Akin to this type of ability test are those that are spatial in nature. These tests often are clearly intended to arouse

imagery, but this imagery is generally concerned with the mental manipulation of spatial relationships.

Clinical Uses of Mental Imagery

Although imagery has been an instrument of therapeutic intervention throughout recorded history, recently interest in imagery techniques has greatly expanded and intensified. Several writers have indicated numerous characteristics of the imagery mode that make it an eminently suitable vehicle for clinical work.

Over the years, numerous widely varied, imagery-based therapies have emerged both abroad and in the United States. Evidence is also accumulating that spontaneous and induced visual images are a rich and readily accessible source of diagnostic information (Sheikh, 2003).

META-ANALYSIS

The fundamental problem addressed by meta-analytic procedures is the cumulation of evidence. There has long been a pessimistic feeling in the softer social, behavioral, and biological sciences that progress has been exceedingly slow, at least when compared to the progress of harder sciences, such as physics and chemistry. In particular, it has seemed that the softer (and newer) sciences do not show the orderly progress and development of the harder (and older) sciences. In other words, the more recent work of the harder sciences seems to build directly upon the older work of those sciences, whereas the more recent work of the softer sciences seems often to be starting from scratch.

Cumulating Scientific Evidence

Poor cumulation does not seem to be due primarily to lack of replication, or to the failure to recognize the need for replication. There are many areas of the softer sciences for which we have the results of numerous studies, all addressing essentially the same question. Our summaries of the results of these sets of studies, however, have not been nearly as informative as they might have been, either with respect to summarized levels of statistical significance or with respect to summarized effect magnitudes. Even the best reviews of research by the most sophisticated workers have rarely told us much more about each study in a set of studies than the direction of the relationship between the variables investigated, and whether or not a given significance level was attained. This state of affairs is beginning to change. More and more reviews of the literature are moving from the traditional literary approach to quantitative approaches to research synthesis. The goals of these quantitative approaches of meta-analysis are to help us discover what we have learned from the results of the studies conducted, and to help us discover what we have not yet learned.

Defining Research Results

Before we can consider various issues and procedures in the cumulation of research results, we must become quite explicit about the meaning of the concept "results of a study." It is easiest to begin with what we do not mean. We do not mean the prose conclusion drawn by the investigator and reported in the abstract, the results, or the discussion section of the research report. We also do not mean the results of an omnibus F test with $df > 1$ in the numerator or an omnibus χ^2 test with $df > 1$. (These omnibus tests address vague questions that are rarely, if ever, of scientific interest.)

What we do mean is the answer to the question: What is the relationship between any variable X and any variable Y? The variables X and Y are chosen with only the constraint that their relationship be of interest to us. The answer to this question should normally come in two parts: (1) the estimate of the magnitude of the relationship (the effect size), and (2) an indication of the accuracy, precision, or stability of the estimated effect size (as in a confidence interval placed around the effect size estimate). An alternative to the second part of the answer is one not intrinsi-

cally more useful, but one more consistent with the existing practices of researchers; that is, the examination of the significance level of the difference between the obtained effect size and the effect size expected under the null hypothesis (usually an effect size of zero). If the significance level is employed, it should always be reported accurately and never as "significant" or "not significant."

Because a complete reporting of the results of a study requires the report of both the effect size and level of statistical significance, it is useful to make explicit the relationship between these quantities. The general relationship is given by:

$$\text{Test of Significance} = \text{Size of Effect} \times \text{Size of Study}$$

In other words, the larger the study in terms of the number of sampling units, the more significant the results will be. This is true unless the size of the effect is truly zero, in which case a larger study will not produce a result that is any more significant than a smaller study. However, effect magnitudes of zero are not encountered very often.

A Brief Historical Note

We are inclined to think of meta-analysis as a recent development, but it is older than the *t*-test, which dates back to 1908! We can simultaneously describe the early history of meta-analysis and provide a classic illustration of the meta-analytic enterprise. In 1904, Karl Pearson collected correlation coefficients (*r*s); there were six of them with values of .58, .58, .60, .63, .66, and .77. The weighted mean *r* of these six correlation coefficients was .64, the unweighted mean *r* was .63, and the median *r* was .61.

Karl Pearson was collecting correlation coefficients because he wanted to know the degree to which inoculation against smallpox saved lives. His own rough-and-ready summary of his meta-analysis of six studies was that there was a .6 correlation between inoculation and survival—a truly huge effect. An *r* of that magnitude can be thought of as the effects of inoculation changing the proportion of people surviving from 20% to 80%.

When Karl Pearson quantitatively summarized six studies of the effects of smallpox inoculation, a meta-analysis was an unusual thing to do. It is unusual no longer. Indeed, there is an explosion of meta-analytic research syntheses such that a rapidly increasing proportion of all reviews of the literature are in the form of quantitative reviews. The trajectory is such that within just a few years virtually all reviews of the literature in the serious scientific journals of our fields will be quantitative reviews—meta-analyses.

MILLER ANALOGIES TEST

The Miller Analogies Test consists of 100 verbal analogy items (A is to B as C is to D) drawn from a wide range of academic areas. It is a highly regarded test with reasonably substantial prediction of academic success of potential students in graduate schools in a variety of departments. It measures verbal and reasoning ability and has the technical characteristics of being able to differentiate among high-ability students of varying potential. The test has been shown to predict grades in graduate school in a broad range of areas, and seems to serve this purpose as well as any predictor available, except for those fields involving considerable quantitative material. This test has been the subject of considerable research to support its claims. The Miller Analogies Test was carefully built and access to it is strictly controlled. It has a high level of difficulty, and good aids to help users interpret the scores on the test.

MIND/BODY PROBLEM

For centuries, scholars have struggled to define the nature of the human being. One of the key questions in this struggle deals with mind, body, and the relationship between them.

There is general agreement that the term "body" refers to the material, physical characteristics of the organism, the activities of which can be studied by the traditional empirical methods of science. There is also general agreement that having a body is at least a part of the nature of being human.

It is the mind (psyche, soul)—the question of whether such an entity exists, and how to define it—that is the crux of the mind/body problem. For some thinkers, the immediate experience of self-awareness constitutes evidence that mind is qualitatively different from the physiological body. At one extreme, the terms *mind* and *mental* have been defined as describing a nonphysical, noncorporeal entity. Such

an entity would not necessarily function according to the same laws as would matter. Its existence would thus logically permit acknowledgment of the possibilities of life after death, extrasensory perception, and other nonmaterial phenomena, as well as more traditional mental functions such as learning, memory, and intelligence. The laws of such phenomena need not necessarily relate to those of the body.

Being nonmaterial and nonphysical, the mind cannot be verified or studied by means of input from the physical senses. This feature of mind causes the mind-–body problem for those who would study human behavior using empirical methods.

In the interest of solving this dilemma, scholars have developed three main approaches to defining mind in a different manner. The first is one of extreme reductionism. From this viewpoint, mind per se does not exist; it is simply a label for a particular level of biological functioning—specifically, the activity of the brain and nervous system.

The second approach tries to relate the qualitatively dissimilar mind and body by learning about the former from empirical knowledge of the latter. This approach is typically illustrated by inferences concerning the nature of mental activities drawn from observation and correlation of externally observable behavioral characteristics. Such an approach, however, leaves the psychologist with the problem of creating a means for relating the internal activity of the mind to the physically observable behavior of the body.

The third approach is in some ways similar to reductionism, but is not as simplistic. In this perspective, neither mind nor body is viewed as an independent entity. Instead, the human being is viewed as a single composite of mind and body, neither of which has existence without the other. Such viewpoints have come to be called "double aspect."

The defining characteristic of these attempts to solve the mind–body problem is whether the particular definition of the mind aspect best lends itself to study of the mind by the method of rationalism, the method of empiricism, or some combination of the two. Thus, the necessity of interpreting psychological and behavioral data in terms of their correlates with the laws of physics and biology (instead of by independent laws of their own) will depend upon the nature of mind and its relationship, if any, to body.

Without being explicit as to their particular philosophical positions on the mind–body problem, neuropsychologists collectively tend to use methodology by which they correlate either brain activity, loci, or neuronal activity patterns with observable behavior, verbal or otherwise. The phenomenal scope of development of modern technology (including MRI, CT scan, etc.) has broadened the range and complexity of behavior comprising the study of neuropsychology.

At the same time, there has been a resurgence of acceptance of "mind" as an appropriate subject of study in and of itself, as well as in its relationship to the body. A particularly salient review article illustrating the scope of mind/body relationships in current neuroscience can be found in DeAngelis (2002).

MINDLESSNESS–MINDFULNESS

Mindlessness may be defined as a state of reduced cognitive activity in which the individual processes cues from the environment in a relatively automatic manner without reference to potentially novel (or simply other) aspects of those cues. Mindfulness, in contrast, is a state in which environmental cues are consciously manipulated, and the individual is engaged in actively constructing his or her environment. This is in marked contrast to the mindless state in which one deals with an already constructed environment.

Mindless information processing may arise either after many repetitions of a particular experience or, in certain instances, after a single exposure. In the former case, as an individual's experience with certain situations accumulates, a cognitive structure of the situation is formed that represents its underlying "semantics." The appearance of similar cues on subsequent occasions will then trigger a mindless sequence of behaviors. Once an activity becomes mindless, the underlying semantics may no longer be available for conscious cognitive manipulation or even for examination. In the latter single-exposure case, reduced cognitive activity does not result from reliance on cognitive structures built up over time, but from reliance on a cognitive structure that one has appropriated from another source.

Mindlessness is pervasive. In fact, for the typical individual, *mindfulness* is expected to occur only (1) when significantly more effort is demanded by the situation than was originally demanded, (2) when the external factors in the situation disrupt initiation or the mindless sequence, (3) when external factors prevent the completion of the behavior, or (4) when negative or positive consequences are experienced that are sufficiently discrepant with the consequences of prior enactments of the same behavior.

Although research has addressed reduced levels of cognitive activity (e.g., automaticity, preattentive processing, and overlearning), a newer theory and a newer term are needed for several reasons. First, mindlessness suggests a more molar unit of analysis than has been examined in the past. Second, mindlessness may come about with and without repeated exposure. Third, mindlessness and mindfulness appear to be qualitatively different, not just quantitatively different (e.g., that which has been processed mindlessly may no longer be available for active conscious cognitive work). Fourth, researchers studying automaticity, for example,

have focused on the adaptive function automatic processing serves in freeing conscious attention. Although this is certainly true, all research conducted thus far on mindlessness–mindfulness suggests that it may also be quite maladaptive.

The study of mindlessness has been pursued in several domains: its consequence for competent performance, for the perception of deviance, and for the course of physical disease, as well as its implications for the very study of social psychological processes.

Research has revealed that whether interactions between people were face-to-face or through written communication, and whether they were semantically sound or senseless, they occasioned behavior that appeared mindless as long as the structure of the interaction triggered some overlearned sequence of behavior. With respect to potentially relevant information, people failed to hear what was said and to read what was written.

Because the individual components of the activity progressively drop out with each repetition of an activity, the result is not only that the individual is responding to some abstracted structure but also that the steps of the task become relatively inaccessible. Thus research has found that counter to an analysis that ignored the mindless–mindful distinction, a great deal of practice at a task may render the individual more vulnerable to external factors that bring competence into question. When these factors led subjects to question whether they could do the task, groups that were moderately practiced were able to supply the steps or the activity as evidence of competence and, therefore, did not show performance decrements. Unpracticed and overpracticed groups could not supply the task components and, therefore, showed clear debilitation.

Regarding the perception of deviance, it was reasoned, first, that deviance (novelty) breeds mindfulness. If people are typically mindless vis-à-vis normal individuals, then the people who are deviant in any respect may be perceived as deviant in many respects (and, therefore, labeled, avoided, etc.) not so much because of their deviance but because of the thorough scrutiny prompted by the mindful state. Such a close examination of *any* individual would lead one to notice characteristics that typically go unnoticed and to inappropriately judge these characteristics as extreme or unusual. As predicted, it was found that the perception of the deviant was accurate, but the typical characteristics and gestures that were noticed were evaluated as extreme and unusual. This occurred whether the deviance was positive (e.g., a millionaire) or negative (e.g., an ex-mental patient) but did not occur when the same stimulus person was not given a deviant label.

Additional research investigated mindlessness on initial exposure, that is, mindlessness that results from the formation of premature cognitive commitments to information. A premature cognitive commitment is considered premature because the individual makes a commitment to information and freezes its meaning before considering alternative uses to which the information could be put.

Research found that encouraging decision making in nursing home residents resulted in these residents being happier, healthier, and more alert. A follow-up study also found that they lived longer than comparison groups. Initially, it was thought that the experimental group was a group for whom the researchers had induced a sense of control and responsibility. Because the elderly, especially the institutionalized elderly, are a group for whom routine is the rule, where there is very little to think about, the experimental group might be better seen as a thought-encouraged group, which would suggest that mindfulness may be necessary for survival. Its primary effectiveness in health-related issues, however, may be due to its ability to provoke mindfulness.

Work on mindlessness also has been conducted in an educational setting. Here it was found that when information is initially given in absolute language (e.g., "this is an X"), people form premature cognitive commitments to the information and are oblivious to future creative uses of that information. When instead people are instructed conditionally (e.g., "this could be X"), alternative uses of the information remain available to them. Indeed, later work found that many of the beliefs we hold about learning are mindless. For example, we believe we should learn the basics so well that they become second nature. Now we know that "second nature" is mindless. We believe we should keep the object of our attention still when we want to pay attention to it. If we mindfully varied the target of our attention, instead, we would find paying attention to be easier. We also believe we should delay gratification and so we think learning is difficult. In fact, mindful learning is what we do at play. Drawing novel distinctions, the essence of mindfulness, is the essence of engagement and thus is immediately gratifying.

Research also suggests that our mindfulness is visible and has an effect on other people. Research participants were asked to draw a picture and then copy their drawing three times. One group, however, was given a mindfulness instruction and was asked to make the last copy new in very subtle ways that only they would be aware of. The drawings were then presented to raters in a random order. We found that those drawings mindfully created were preferred. In another investigation, children interacted with an adult whose behavior was either scripted or not. Although the essence of the verbal content was the same, those who interacted with a mindless adult showed a drop in self-esteem.

Research on mindlessness and mindfulness has yielded a wealth of results, spanning a number of diverse issues unified by a common theme: the consequences of reduced cognitive activity. The findings thus far suggest that mindlessness–mindfulness is a central dimension in human functioning, the study of which may perhaps even yield basic laws of human behavior.

MINNESOTA MULTIPHASIC PERSONALITY INVENTORY (MMPI-2)

The most widely researched and used clinical assessment instrument is the Minnesota Multiphasic Personality Inventory (MMPI-2). The MMPI was originally published in the 1940s to assess mental health problems in psychiatric and medical settings, and it rapidly became a standard personality instrument in a wide variety of settings (Hathaway & McKinley, 1940). The popularity of the true-false personality inventory was due in large part to its easy-to-use format and to the fact that the scales have well established validity in assessing clinical symptoms and syndromes (Butcher, 1999). The MMPI underwent a major revision in the 1980s, resulting in two forms of the test—an adult version, the MMPI-2 (Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989), and an adolescent form, MMPI-A (Butcher et al., 1992). The MMPI-2 is a 567-item inventory comprised of symptoms, beliefs, and attitudes in adults above age 18. The MMPI-A is a 467-item version that is used for assessing young people from ages 14 to 18. This discussion will address only the MMPI-2.

Assessing Protocol Validity

Some people in some settings, when taking psychological tests, are motivated to present themselves in ways that do not disclose accurate information about themselves. For example, in cases where a person is being tested to determine sanity in a pretrial criminal evaluation, the person might be exaggerating symptoms. The initial step in MMPI-2 profile interpretation is the important one of determining whether the client has cooperated with the testing and responded in a frank, open manner. A number of indices are available on the MMPI-2 to aid the clinician in determining whether the client's item responses provide key personality information, or whether they are simply reflecting response sets or deceptive motivational patterns that disguise the true feelings and motivations of the client (Baer, Wetter, Nichols, Greene, & Berry, 1995). Several validity scales have been developed to evaluate the client's approach to the test. Four of these assessment strategies will be described here.

The L Scale

The L scale is a measure of the client's willingness to acknowledge personal faults or problems. Individuals who score high on this scale are presenting an overly favorable picture of themselves. High scorers are claiming virtue not found among people in general. The L scale is particularly valuable in situations like personnel screening or some types of court cases, because people in those settings try to put their best foot forward and present themselves as "better" adjusted than they really are.

The K Scale

The K scale was developed to assess test defensiveness or the tendency to minimize problems. This scale, in addition to serving as an index of defensiveness, serves also as a correction factor to compensate for the tendency of some people to deny problems.

The F Scale

The F scale was developed to assess the tendency of some people to exaggerate their problems or "fake" the test by overresponding to extreme items. The items on this scale are very rare or bizarre symptoms. Individuals who endorse a lot of these items tend to exaggerate symptoms on the MMPI-2, perhaps as a way of trying to convince professionals that they need psychological services. As noted earlier, this motivational pattern is also found among individuals with a need to claim problems in order to influence the court in forensic cases. The F scale can be elevated for several possible reasons. The profile could be invalid because the client became confused or disoriented or responded in a random manner. High F scores are also found among clients who are malingering or producing exaggerated responses in order to falsely claim mental illness (Graham, Watts, & Timbrook, 1991).

TRIN and VRIN Scales

Two inconsistency scales for determining profile validity have been developed in the MMPI-2. These scales are based on the analysis of the individual's response to the items in a consistent or inconsistent manner. The scales are comprised of item pairs that involve responses that are semantically inconsistent; for example, a pair of items that contain contradictory content that cannot logically be answered in the same direction if the subject is responding consistently to the content.

Assessing Clinical Symptom Patterns

The assessment of clinical problems is approached in several ways through the self-reported symptoms and behaviors. We will examine three types of scales that comprise the MMPI-2's problem measures: the traditional clinical scales and profile codes, the MMPI-2 content scales, and the specific problems or supplemental scales. A scale is a group of items from the MMPI-2 item pool that have been shown to measure certain symptom patterns or personality traits. Each item cluster or scale is "normed" on a population of normal individuals. This normative group serves as the reference point to which all profiles are compared.

The MMPI-2 Clinical Scales

The authors of the original MMPI developed the clinical scales to empirically group patients into clinical problem

types. For example, they developed scales to assess hypochondriasis (The Hs scale), depression (the D scale), hysteria (the Hy scale), psychopathic deviation (the Pd scale), paranoid thinking (the Pa scale), psychasthenia (the Pt scale), schizophrenia (the Sc scale), and mania (the Ma scale). In addition, two other scales were included on the clinical profile to address problems of sex role identification (the Mf scale) and social introversion and extraversion (the Si scale). In addition to interpretation of single clinical scales, elevations on certain scale patterns or configurations of scores (referred to as profile or code types) are interpreted. These profile types result from clients endorsing two or more of the clinical scales.

Content-Based Scales

The MMPI-2 contains a number of scales that assess the content themes an individual endorses in the item pool. The content scales are homogeneous item clusters that assess unitary themes and represent clear communication about problems to the practitioner. There are 15 content scales measuring different symptom areas and problems; examples include Antisocial Practices (ASP), Bizarre Mentation (BIZ), and Family Problems (FAM).

Special Scales

Several supplemental scales have been developed to assess specific problems, such as the potential to develop problems of addiction (the MacAndrew Addiction Scale or MAC-R, and the Addiction Potential Scale or APS) and whether or not the individual acknowledges having problems with drugs or alcohol. The Marital Distress Scale assesses clients' attitudes toward their marital relationship. These special scales allow the practitioner to assess specific problems that are not addressed in the clinical or content scales.

How the MMPI-2 Is Used

There are many diverse, current applications for the MMPI-2 for evaluating individuals across a wide variety of settings. Contemporary uses include: evaluating clients who are being admitted to an inpatient psychiatric facility; understanding problems and possible treatment resistance of clients entering psychotherapy; providing personality information for therapists to employ in giving the client feedback in psychotherapy; assessing possible personality problems of students applying for a graduate clinical psychology program; measuring behavior problems and symptoms in neuropsychological evaluation of a client with severe head injury; appraising personality factors and psychological adjustment in applicants for an airline pilot position; examining persons who are being tried for murder and are claiming to be not guilty by reason of insanity; and using the test as a research instrument to evaluate the psychological changes in a drug trial. There have been over 25 translations and adaptations of the MMPI-2 for use in other countries. The items and scales have shown remarkable robustness when used in other languages and cultures (Butcher, 1996).

In summary, the MMPI-2 is a self-report personality inventory that provides the test user with scores on a number of scales. These scales assess response attitudes, mental health symptoms and personality traits, and special problems that the client might be experiencing. The MMPI-2 has been widely validated and is used in numerous settings around the world.

MOB PSYCHOLOGY

Crowds are defined as "co-acting, shoulder-to-shoulder, anonymous, casual, temporary, and unorganized collectivities" (Brown, 1954, p. 840). According to Floyd Allport (1924), "A crowd is a collection of individuals who are all attending and reacting to some common object, their reactions being of a simple prepotent sort and accompanied by strong emotional responses" (p. 292). Crowds can be subdivided according to whether they are active or passive, the former being a *mob* and the latter an *audience.*

Mobs are further classified according to the dominant behavior of participants: (1) aggressive, (2) escape, (3) acquisitive, or (4) expressive. *Aggressive* mobs, which include

riot and lynch mobs, involve a display of aggression toward persons or objects. The dominant behavior of *escape* mobs is one of panic, as during a fire in a theater. Orderly escape is not panic. According to Brown (1954), "Panic is emotional and irrational. The escape behavior of the fear-driven mob must either be maladaptive from the point of view of the individual, or, if personally adaptive, the behavior must ruthlessly sacrifice the interests of others who also seek to escape" (p. 858). *Acquisitive* mobs are similar to escape mobs in that both involve a competition for some object that is in short supply—tickets to the theater in the case of the acquisitive mob, and exits from the theater in the case of the escape mob. *Expressive* mobs represent a wastebasket category that includes all mobs not in the first three categories. Included here is behavior that can best be described by the obsolete word *revelous:* behavior that might be displayed at religious revivals, sporting events, and rock music concerts. LaPiere (1938) believed that such behavior provides a release for the psychological tensions created by social life.

While there is no universal agreement among theorists, certain features tend to be attributed to mobs: (1) like-mindedness or "mental homogeneity," and (2) emotionality. Gustav Le Bon (1903), in his classic work, *The Crowd,* explained the mental homogeneity of mobs in terms of *contagion*—a mechanical, disease-like spreading of affect from one member to another. More recent research (Hatfield, Cacioppo, & Rapson, 1994) suggests that contagion is not mechanical, but rather is dependent on a number of conditions. Milgram and Toch (1969) suggest that the mechanism of *convergence* may also account for the seeming mental homogeneity of mobs: like-minded individuals tend to converge and join mobs. Thus, homogeneity precedes rather than follows from membership in the mob. Brown (1954) questioned the homogeneity of aggressive mobs and suggested that the composition of such mobs could be ordered in terms of mob members' readiness to deviate from conventional norms of society. He identified five types of participants, ranging from the "lawless" whose actions "trigger" the mob, to those "supportive onlookers" who stand on the fringes shouting encouragement.

A central issue in the study of mob behavior is determining why restraints that lead to conventional behavior break down when individuals find themselves in a crowd. Two important mechanisms that account for the violation of conventional behavior in crowds are: (1) the loss of responsibility through anonymity, and (2) the impression of universality. Both mechanisms are enhanced by the size of the crowd. Le Bon (1903) and many others have pointed out that aggressive mob members find it easier to act out their impulses because of the difficulty legal authorities have in singling them out and holding them responsible for their actions. Mob participants will feel safer from legal reprisals in large crowds because the sheer size of the crowd will pose impediments to identification and apprehension by the authorities. Allport (1924), and more recently, Turner and Killian (1957) have contended that an individual is swayed by the mob because of a belief that if everyone else is acting in a certain way, the actions cannot be wrong—the mob simply redefines the norm for "correct" behavior. In their "emergent norm theory," Turner and Killian (1957) take issue with the causal role of emotional contagion, and argue instead that people act the way they do in crowds because the crowd helps to define the situation and the appropriate behavior. In the crowd context, the *less* anonymous one is to coacting peers, the greater the conformity to crowd norms. The greater the number of crowd participants, the stronger the impression of universality. Crowd size has different implications for aggressive as opposed to acquisitive and escape mobs. Whereas in aggressive mobs, a larger number of crowd members enhances belief in anonymity and impressions of universality, in acquisitive and escape mobs, a large number of crowd members increases the competition for scarce resources (e.g., theater tickets, escape exits), thereby amplifying crowd responses.

Mob psychology has attracted little attention from social psychologists in recent years, owing in part to methodological difficulties in studying such phenomena. The last edition of the *Handbook of Social Psychology* to feature a chapter on mob psychology was published in 1969. Similarly, recent social psychology textbooks no longer include a chapter on mob psychology; the last one to do so was written by Roger Brown in 1965.

MODELING

Psychological theories have traditionally emphasized learning through the rewarding and punishing effects that actions produce. Yet, if knowledge and competencies could

be acquired only by direct experience, human development would be severely retarded, not to mention unmercifully tedious and perilous. A given culture could never transmit the complexities of its language, mores, social practices, and essential competencies if they had to be shaped laboriously in each new member solely by response consequences, without the benefit of models to exemplify the cultural patterns. Trial-and-error experience can be a tough teacher; errors can be highly costly and some missteps are deadly. The abbreviation of the acquisition process is, therefore, vital for survival as well as for successful human development. Moreover, the constraints of time, resources, and mobility impose severe limits on the situations and activities that can be directly explored for the acquisition of knowledge and competencies.

Humans have evolved an advanced capacity for learning by observation that enables them to develop their knowledge and competencies from information conveyed by modeling influences. Indeed, virtually all types of behavioral, cognitive, and affective learning resulting from direct experience can be achieved vicariously by observing people's behavior and its consequences for them (Bandura, 1986; Rosenthal & Zimmerman, 1978).

Much human learning occurs either deliberately or inadvertently by observance of the actual behavior of others in one's social environment and the consequences they experience. However, a great deal of information about human values, styles of thinking, behavior patterns, and sociostructural opportunities and constraints is gained from modeled styles of behavior portrayed symbolically through the electronic mass media. The growing importance of symbolic modeling lies in its tremendous scope and multiplicative power. A single model can transmit new ways of thinking and behaving to multitudes of people in widely dispersed locales simultaneously. The accelerated development of electronic technologies has vastly expanded the range of models to which members of society are exposed day in and day out. These electronic systems, feeding off telecommunications satellites, have become the dominant vehicle for disseminating symbolic environments. By drawing on these modeled patterns of thought and action, observers transcend the bounds of their immediate environment.

Not only are social practices being widely diffused within societies, but ideas, values, and styles of conduct are being modeled worldwide. The electronic media are coming to play an increasingly influential role in transcultural and sociopolitical change (Bandura, 1997; Braithwaite, 1994). Because the electronic media occupy a large part of people's lives, the study of acculturation in the present electronic age must be broadened to include electronic acculturation.

Mechanisms of Observational Learning

Observational learning is governed by four component subfunctions. *Attentional processes* determine what people selectively observe in the profusion of modeling influences and what information they extract from ongoing modeled events. Observers' preconceptions, cognitive development, interests, and value preferences influence what they explore and how they perceive what is modeled in the social and symbolic environment.

People cannot be much influenced by modeled events if they do not remember them. A second subfunction concerns *cognitive representational processes.* Retention involves an active process of transforming and restructuring information about modeled events into rules and conceptions for generating new patterns of behavior. In the third subfunction in observational learning—the *behavioral production process*—symbolic conceptions are transformed into appropriate courses of action. Skills are usually perfected through a conception-matching process. Conceptions guide the construction and execution of behavior patterns and the behavior is modified as necessary to achieve close correspondence between conception and action.

The fourth major subfunction concerns *motivational processes.* People do not perform everything they learn. Performance of styles of behavior acquired through modeling are influenced by three types of incentive motivators—direct, vicarious, and self-produced. People are more likely to perform observationally-learned behavior if it results in valued outcomes for them than if it has unrewarding or punishing effects. The observed detriments and benefits experienced by others influence the performance of modeled patterns in much the same way as do directly experienced consequences. People are motivated by the successes of others who are similar to themselves, but discouraged from pursuing courses of behavior that they have seen often result in adverse consequences. Personal standards of conduct provide a further source of incentive motivation. People pursue activities they find self-satisfying and that give them a sense of self-worth but reject those of which they personally disapprove.

Abstract Modeling

Social modeling is not merely a process of behavioral mimicry. Highly functional patterns of behavior, which constitute the proven skills and established customs of a culture, may be adopted in essentially the same form as they are exemplified. There is little leeway for improvisation on how to drive automobiles. However, in many activities, subskills must be improvised to suit different situations. Modeling influences can convey rules for generative and innovative behavior as well. For example, an individual may see others confront moral conflicts involving different matters yet apply the same moral standard to each of them. In abstract modeling, observers extract the rules or standards governing specific judgments differing in content but embodying the same underlying rule. Once people extract the rules, they can use them to judge things and generate new courses of behavior that fit the prototype but go beyond the examples they have seen or heard. Evidence that generative

rules of thought and behavior can be created through abstract modeling attests to the broad scope of observational learning (Bandura, 1986; Rosenthal & Zimmerman, 1978).

Modeling can contribute to creativeness in several ways. Originality largely involves synthesizing experiences into new ways of thinking and doing things. When exposed to models of differing styles of thinking and behaving, observers often vary in what they adopt from the different sources and thereby create new blends of personal characteristics that differ from the individual models. Modeling influences that exemplify new perspectives and innovative styles of thinking also foster creativity by weakening conventional mind-sets.

Motivational, Emotional, and Valuational Effects

In addition to cultivating competencies, modeling influences can alter incentive motivation (Bandura, 1986). Seeing others achieve desired outcomes by their efforts can instill motivating outcome expectations in observers that they can secure similar benefits for comparable performances. These motivational effects rest on observers' judgments that they have the efficacy to produce the modeled attainments and that comparable accomplishments will bring them similar beneficial outcomes. By the same token, seeing others punished for engaging in certain activities can instill negative outcome expectations that serve as disincentives.

People are easily aroused by the emotional expressions of others. What gives significance to vicarious emotional influence is that observers can acquire lasting attitudes and emotional and behavioral proclivities toward persons, places, or things that have been associated with modeled emotional experiences. They learn to fear the things that frightened models, to dislike what repulsed them, and to like what gratified them (Bandura, 1992). Fears and intractable phobias are ameliorated by modeling influences that convey information about coping strategies for exercising control over the things that are feared (Bandura, 1997; Williams, 1992). Values can similarly be developed and altered vicariously by repeated exposure to modeled preferences. The actions of models can also serve as social prompts that activate, channel, and support previously learned behavior. Thus, the types of models that prevail within a social milieu partly determine which human qualities, from among many alternatives, are selectively encouraged.

During the course of their daily lives, people have direct contact with only a small sector of the physical and social environment. In their daily routines, they travel the same routes, visit the same familiar places, and see the same group of friends and associates. As a result, their conceptions of social reality are greatly influenced by modeled representations of society in the mass media (Gerbner, 1972). The more their conceptions of the world around them depend on portrayals in the media's symbolic environment, the greater the media's social impact (Ball-Rokeach & DeFleur, 1976).

Social Diffusion through Symbolic Modeling

Much of the preceding discussion has been concerned with modeling at the individual level. As previously noted, the electronic media are coming to play an increasingly powerful role in transcultural change. In this broader function, symbolic modeling usually serves as the principal conveyer of innovations to widely dispersed areas, especially in early phases of diffusion. Modeling instructs people in new ideas and social practices and designates their functional value.

A number of factors, including perceived self-efficacy to execute the modeled patterns, possession of necessary resources, outcome expectations concerning the costs and benefits of the new styles of behavior in the new milieu, and perceived opportunities and impediments, determine whether people will adopt and put into practice what they have learned observationally (Bandura, 1986, 1997).

People are enmeshed in networks of relationship. They are linked, not only directly, by personal relationships. Because acquaintanceships overlap different network clusters, people become linked to each other indirectly by interconnected ties. These multi-linked social networks provide diffusion paths for the spread of new ideas, lifestyle patterns, and social practices (Granovetter, 1983; Rogers & Kincaid, 1981).

MONISM/DUALISM

Monism/dualism refers to a traditional classification of the various types of solutions proposed for the mind–body problem. Such solutions assume that the human being comprises either a single, unified entity (monism) or two qualitatively different, independent entities (dualism). Adherents of each type of solution also tend to differ in epistemology. Monists tend to view empiricism as the primary (even the only) acceptable method of knowledge. Dualists, on the other hand, accept empiricism and rationalism as equally appropriate and valid, each in its own sphere.

Because monists tend to equate knowledge with empiricism, all of their definitions try to equate or reduce mind (or mental functions) to the activity of the brain and nervous system. Thus, in effect, mind and body become one. Mind is defined as being of the materialistic order of things. In the field of psychology, this position gives neuroscience a central focus of importance in the understanding and explanation of behavior. Many neuropsychologists thus view the study of the brain and nervous system as the primary approach to understanding human behavior.

Dualists, in contrast, are faced with the problem of relating the activities of the nonmaterial mind and the material body. Two primary patterns of dualism have prevailed throughout history. The first are the interactionist theories, of which the views of Descartes are considered classic. Modern dualists have not had much success in replacing Descartes's explanation in terms of modern neurological knowledge.

A form of dualism that avoids the difficulty of explaining an interaction is psychophysical parallelism. Mind and body are viewed as acting in concert such that events that affect the one, affect the other; thus, knowledge of one provides information about the other. The isomorphism of mental activity and brain function, as well as the applications of the concepts of topology and field theory by Gestalt psychology, represent a modern version of psychophysical parallelism in present-day thinking.

A key element of dualistic positions as they affect psychology is that when the mind is defined as being a totally separate entity from the materialistic body, conceptualizations of the activity of the mind are not constrained by the laws of materialism. Thus, although mental activity may parallel physiological (or physical) activity, there is no necessity for it to do so. Laws unique to mental activity become acceptable and appropriate. The study of cognitive activity without concern for or consideration of any underlying nervous system activity has led to many attempts to develop such laws of behavior.

Although it is self-evident that the relating of psychological, especially cognitive, behavior to physiological activity implies the taking of a position on the monism-dualism problem, few neuropsychologists (either clinical or research) ever explicitly state a position. However, since the days when Watsonian behaviorism made its great impact, American psychology has been heavily monistic, and the monistic position still prevails in this discipline. Nevertheless, the rise in popularity of existentialism, humanism, and other self-oriented philosophies and their effects on the thinking of psychologists, particularly psychotherapists, have led to revived interest in problems that logically require dualistic positions. Such areas of concern as imageless thought, life after death, and mental telepathy have aroused the interest of serious scientists. Concomitantly, there has arisen new interest in dualism.

MORAL DEVELOPMENT

Moral development involves the process by which persons internalize and orient their behavior according to socially sanctioned rules. Three conceptually distinguishable aspects of this developmental process have been highlighted: moral judgment (how one reasons about moral situations), moral behavior (how one acts), and moral emotions (what one feels).

Moral Judgment

Early in the twentieth century, psychologists like James Mark Baldwin and William McDougall began to study the process of moral development. Much contemporary research, however, has been inspired by the cognitive-developmental theory of Jean Piaget (1932). According to Piaget's two-stage account, children progress from a heteronomous morality of constraint to an autonomous morality of cooperation. Although the stages differ on a number of dimensions—including employment of expiatory punishment versus restitution, belief in immanent justice, and unilateral obedience to authority—most research has examined whether moral judgments are based on objective consequences or subjective intentions. In general, research supports an age-related shift from an objective to a more subjective (intentional) conception of moral responsibility.

Kohlberg (1958) extended Piaget's two-stage view by postulating that moral rules and principles are progressively internalized throughout adolescence and into adulthood. The theory comprises three general levels of moral reasoning: preconventional, conventional, and postconventional morality. Each level, in turn, is divided into two specific stages (Kohlberg, 1958).

Preconventional morality is externally oriented. At Stage 1, what is right is defined by avoiding punishment and obeying authority. At Stage 2, hedonistic acts that satisfy personal needs determine what is right. Moral deci-

sions at the *conventional* level are mediated by internalized rules and values. At Stage 3, interpersonal conformity is emphasized; one adheres to rules in order to please and be approved of by significant others. At Stage 4, right is defined in terms of doing one's duty and maintaining the existing social order.

Postconventional reasoners emphasize moral principles with applicability and validity independent of a specific authority or social order. At Stage 5, moral decisions reflect a personal obligation to abide by contractual commitments, including implicit societal contracts. People understand the relativistic nature of rules and laws, but realize the need for contractual agreements to ensure equal justice and protect individual rights. However, rational considerations about social utility may necessitate subsequent changes and revisions of existing laws. At Stage 6, moral decisions are grounded in self-selected rational ethical principles considered to be universally valid.

The central tenet of Kohlberg's formulation—namely, a fixed moral developmental sequence—has been supported by empirical investigations. In particular, research supports the supposition that preconventional morality is a prerequisite for conventional reasoning and both must precede the development of postconventional morality (Colby, Kohlberg, Gibbs, & Lieberman, 1983; Walker, 1989). However, the postconventional stages may not necessarily be found in all samples of adolescents or adults, especially Stage 6, which has been deleted in the revised scoring method (Colby & Kohlberg, 1987).

Critics have underscored the role that social-cultural factors may play in promoting postconventional reasoning, especially experiences within the context of a constitutionally based system of justice. Although Kohlberg's model may not provide *the* universal view of a moral person, it does seem to be relevant to people living in countries with constitutionally based legal systems.

Moral Behavior

The empirical link between moral cognition and action has been elusive: people can exhibit the same behavior for different reasons, and individuals at the same level of moral reasoning may act in different ways. Although some linkages have been reported, relationships between moral reasoning and behavior may not be linear (e.g., Hann, Smith, & Block, 1968). If moral behavior is mediated by moral reasoning, it may be necessary to focus on intraindividual variation over time and situations. For example, knowing that people are conventional moral reasoners may not be sufficient to accurately predict their behavior; the specific normative rules or expectations they hold would also need to be identified. Other relevant factors may include knowing how personally committed people are to translating their reasoning into action and the extent to which they possess the self-regulatory resources to do so.

In the 1920s, a more fundamental issue of moral behavior was addressed by Hartshorne and May. They devised behavioral measures of the extent to which participants would resist the temptation to lie, cheat, and steal in experimental settings. Correlational analyses provided little evidence for a general personality trait of honesty; they advanced the position that moral behavior was situation-specific. Research has continued to support the situation-specificity doctrine of moral behavior (Bersoff, 1999). Of course, not all people yield when confronted by situational temptations and external pressures. Recent research has highlighted the role that individual differences in self-regulatory resources may play in impulse control, temptation resistance, and self-restraint (Baumeister, Heatherton, & Tice, 1994).

Moral Emotion

The psychoanalytic theory of guilt-motivated morality was presented by Sigmund Freud. Briefly, Freud contended that children experience Oedipal/Electra feelings. Fear of paternal retaliation prompts them to introject the same-sexed parent's rules and prohibitions: the superego or conscience is thereby formed. In subsequent situations, children experience self-punishment or guilt when tempted to violate these internalized rules. Research indicates, however, that power-assertive parental practices are associated with an externalized morality: children comply with normative standards because they fear detection and/or punishment (Hoffman, 1994). A more internalized morality results when parental discipline is coupled with explanations about the harmful consequences of children's behavior for others. Such practices may contribute to moral development by enhancing children's tendencies to anticipate the consequences of their actions and to empathically experience another's emotional state (Hoffman, 1994).

The development of postconventional moral reasoning and prudent, inner-directed moral behavior are both associated with principles and explanations that emphasize individual rights and the negative impact that misdeeds have on others. Knowing that people are postconventional moral reasoners, however, may not be sufficient for predicting how they will behave in moral situations. The specific principles they are personally committed to, their motivation to implement them, and whether or not they have sufficient self-regulatory resources may also need to be taken into account.

MORPHINE

Morphine is the principal alkaloid of opium, and is used for the control of moderate to severe pain. The word *opium* itself is derived from the Greek name for juice, the drug being obtained from the juice of the poppy, *Papaver somniferum.* Opium contains more than 20 distinct alkaloids. In 1806, Setürner reported the isolation of an opium alkaloid that he named morphine after Morpheus, the Greek god of dreams.

Morphine and other morphinelike drugs (heroin, codeine, or methadone) produce analgesia primarily through their interaction with opioid receptors located in the central nervous system and periphery. The existence of multiple opioid receptors was proposed in 1977 and confirmed by various studies. Soon after the demonstration of these opioid receptors, three classes of endogenous opioid peptides were isolated and identified: the enkephalins, the endorphins, and the dynorphins (Gutstein & Akil, 2001).

Although there are now many compounds with pharmacological properties similar to those produced by morphine, this "old" drug remains the most useful in clinical settings. However, in spite of its efficacy, morphine treatment has some associated problems. Side effects such as nausea, vomiting, constipation, drowsiness, confusion, and the variability in analgesic response between patients are common clinical problems during morphine therapy, with respiratory depression being a less frequent but more serious side effect (Martindale, 2002). Although the development of dependence and/or tolerance is not generally a problem when morphine is used in patients with opioid-sensitive pain, the possibility of tolerance, dependence, and addiction with long-term use may complicate its clinical use and can create barriers to its adequate prescription (Schafer et al., 2001). In fact, the development of tolerance, physical dependence, and addiction with repeated use is a characteristic feature of all the opioid drugs. Tolerance can be defined as a loss of potency of a drug after its repeated administration, so that doses have to be increased to achieve the same effect. Drug addiction of the morphine type is a state arising from repeated administration of morphine or morphinelike drugs (heroin, pethidine, etc.); it is characterized by an overwhelming need to continue taking the drug or one with similar properties. Abrupt withdrawal of morphine or morphinelike drugs from persons physically dependent on them precipitates a withdrawal syndrome (Martindale, 2002). However, when morphine and morphinelike drugs are used correctly in appropriate doses to treat morphine-sensitive pain, tolerance, dependence, and severe side effects are not a clinical problem (McQuay, 1989). What happens when morphine or opioids are given to someone in pain is different from what happens when they are given to someone not in pain (McQuay, 1999). In patients, tolerance may be due to a disease progression or increased nociception, and they may develop a drug-seeking behavior that represents an attempt to get appropriate pain relief (Schug, Merry, & Acland, 1991).

During morphine treatment, common side effects such as nausea, constipation, and drowsiness are usually controlled by appropriate measures. What complicates morphine use in the clinical setting is the variability between patients in their pharmacological responses. Careful evaluation of the morphine dose required to alleviate the pain is needed, given that the effective dose varies not only from patient to patient but also from time to time (because of disease progression and/or tolerance). The correct dose for the patient is that which gives good pain relief during the interval between doses, without producing unacceptable side effects. Another fact that complicates morphine pharmacology is its *pharmacokinetics:* what the body does to the drug. Pharmacokinetics deals with absorption of the drug from the site of administration (oral, rectal, intramuscular), its distribution into the body, its biotransformation, and its elimination from the body. Morphine is a very versatile drug because it can be administered by many differ-

ent routes (oral, parenteral, spinal). When administered orally, it undergoes extensive biotransformation or metabolism, mainly in the liver. Biotransformation of morphine also occurs when it is administered by other routes, but to a lesser extent. For this reason, oral doses must be much larger than parenteral doses to achieve the equivalent effect. The biotransformation of morphine produces two major and important metabolites, morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G). These metabolites are found in the plasma and cerebrospinal fluid after administration of morphine. M6G has pharmacological activity and a more potent antinociceptive effect than morphine. M3G produces stimulatory effects but is devoid of analgesic activity. There are, however, conflicting reports of its effects (antagonism) on morphine and M6G analgesia (Smith, Watt, & Cramond, 1990; Suzuki, Kalso, & Rosenberg, 1993; Faura, Olaso, Garcia Cabanes, & Horga, 1996). It has been suggested that these metabolites may contribute to the global effects of morphine, but the pharmacological activity and real contribution of morphine metabolites remains a mystery despite many years of investigation (Faura, Collins, Moore, & McQuay, 1998).

Given the pharmacological activity of the morphine metabolites and their possible contribution to the global effects of morphine, it is important to specify the factors that can modify the morphine-metabolite relationship. Age of the patient, presence of renal impairment, and route of administration are important factors in the kinetics of morphine and its metabolites. There is evidence that newborn children produce morphine metabolites at a lower rate than children or adults, mainly because of their functional immaturity. Morphine metabolites are eliminated from the body mainly via the kidneys, which is why the presence of renal impairment results in their high plasma concentrations. Intravenous, intramuscular, and rectal administration of morphine result in lower metabolite production than does oral administration (Faura, Collins, Moore, & McQuay, 1998). Although some factors affecting the kinetics of morphine and its metabolites have been determined, the cause of variation in the pharmacological response of morphine remains unknown (Bowsher, 1993).

The available information on morphine confirms that despite the relative lack of knowledge about its pharmacology, this old drug is still the standard against which other analgesic drugs are compared. Its efficacy and safety when properly used make morphine the drug of choice for moderate to severe opioid-sensitive pain.

MORPHOLOGY

Morphemes are the meaningful elements that comprise the internal or sublexical structure of words. Work on the role of sound structure in language processing is common, but only recently have psychologists begun to examine morphemes as units of sublexical processing. Much of the work on morphemes (morphology) focuses on how language users store and understand words composed of more than one morpheme (complex words) and how they create new ones. Compare the English words *indent, indented,* and *indenture.* There is no way to break down the word *indent* into smaller parts whose meanings together make up the meaning of the whole word, but *indented* and *indenture* each consist of the base morpheme, *indent,* and an affix, either *ed* or *ure.* Most complex words can be described in terms of rules for combining components. In the case at hand, the rules generate a past tense or a nominal from the base morpheme. However, not all complex words can easily be described in these terms. For example, we can tell that the word *forget* consists of the prefix *for* and the base *get,* because *forget* has the same irregular past tense form as *get: got.* Yet there is no rule in modern English forming *forgot* from *get.*

The final component of *fullness* is the suffix *ness.* Its function is to form a noun. It is joined together with the first component, the base adjective *full,* to form a noun with the predictable meaning "condition of being full." The same suffix occurs in many other nouns derived from adjectives (e.g., *fondness, fussiness*) and can also be used to form novel words like *nerdiness* or *emotiveness* whose meanings are understood easily by speakers of English. The fact that nouns like *walkness* or *tableness* are awkward also tells us that there are restrictions on how morphemes combine. Morphemes that appear before or after the base morpheme are called affixes (prefixes and suffixes, respectively). Affixes may vary quite widely in their productivity, the likelihood that they will be used to create new words. Compare the two English suffixes *-ure* and *-ness,* both of which form nouns from adjectives (e.g., *indenture* and *sadness*). The first suffix is completely unproductive in modern English; no new word with this suffix has been added to the language in centuries. The second is highly productive: innovations are common.

Languages differ greatly in the prevalence of complex words and in the way in which morphemes combine to make complex words. Some languages (e.g., Chinese) have very little in the way of combining morphology. Others (e.g., Turkish) are famous for their complex morphology, combining many morphemes within a single word. Rules for combining morphemes also vary across languages. In Serbian or English, for example, morphemes are linked linearly (e.g., *un+forget+ful+ness*). In Hebrew, morphemes can be interleaved with one another (e.g., N-F-L combines with -a-a- to form NaFaL, meaning "he fell," and with -o-e- to form NoFeL, meaning "he falls").

Suffixes such as *ure* and *ness* are examples of derivational affixes, whereas *ed* is an inflectional morpheme. Adding a derivational affix forms a new word and often changes the word class of the base morpheme, as in the *indent, indenture* example above. Derivational formations tend to be semantically somewhat unpredictable, as is also true with this example. Compare, for example the relation of *confess-confession* to *profess-profession.* Inflectional morphology is concerned with the different forms that a word may take, depending on its role in a sentence. English is quite poor inflectionally, but in many other languages (e.g., Serbian or Swahili) each noun, verb, and adjective will have a large number of inflected forms.

Words that are morphologically related tend to have similar orthographic and phonological forms as well as similar meanings. Knowledge about words comprises the mental lexicon. A major research question for psycholinguists is whether morphological knowledge is explicitly represented in the mental lexicon or whether it falls out of the conjoint but nonadditive contributions of similarity from form and meaning. Among theorists who think that morphology is explicitly represented, some describe morphological knowledge in terms of lexical representations that are decomposed into constituent morphemes. Others describe morphological knowledge in terms of a principle of lexical organization among full forms that are related. Another point of discussion is whether all word forms, or only those forms that are irregular with respect to either form or meaning, are stored as wholes in the mental lexicon. When regularity is defined with respect to form, we can ask whether words that undergo a change such as *forget-forgot* are represented differently from words such as *forfeit* whose past tense form (*forfeited*) is regular. When regularity is defined in terms of meaning, we can ask whether the meaning of the base morpheme must be semantically transparent with respect to the complex form in order to be represented in the lexicon in terms of its morphological structure. Similarly, we can ask whether inflected and derived forms are represented in the same manner.

In the psycholinguistic literature, a classical task for exploring morphological knowledge is the lexical decision task. Letter strings are presented visually and skilled readers must decide whether each is a real word. Decision latencies tend to be faster for words composed from frequent than from less frequent components. When words are presented in pairs, a prime and then a target, the temporal interval can vary. Sometimes prime and target are presented in immediate succession at varying intervals. Other times there are intervening items. Decision latencies to the target as a function of the type of prime are measured.

Whether or not reduced similarity in spelling or pronunciation between *forget-forgot* type relatives diminishes the magnitude of facilitation to targets relative to *indent-indented* type pairs appears to depend on the timing relation between them. With respect to meaning, results in Hebrew, Dutch, and Serbian have shown morphological facilitation with semantically opaque as well as transparent morphological relatives. However, there is some evidence that at long (250 milliseconds) but not at very short (50 milliseconds) time intervals, morphological facilitation is greater after semantically transparent morphological relatives than after those that are semantically more opaque. Similarly, facilitation for targets tends to be greater after inflectional than after derivational relatives.

Morphemes and their properties play a critical role in word recognition. Morphology cannot be expressed in terms of similarity of form or meaning alone, although facilitation among morphological relatives is sensitive to similarity of form and meaning. Psychologists study morphology for what it reveals about how the components of words (sublexical structure) contribute to word identification and production.

MOTION PARALLAX

Various types of information contribute to the visual perception of depth, including binocular disparity—difference between the retinal images due to the separation of the eyes—and pictorial cues such as relative size and interposition. Relative size refers to the difference in visual size according to the distance from the observer of objects of known physical size, while interposition refers to the fact that a relatively close object can partially or totally hide a more distant object. Another source of information derives from the observer's motion. This is *motion parallax*—systematic visual motion of the static environment. The direction of visual motion is opposite to the observer's motion for objects in front of fixation and in the same direction for objects behind fixation; rates of visual motion increase with increasing distance from fixation. Motion parallax also applies to a surface slanted in depth: The visual geometry transforms with the observer's motion, according to the degree of slant. Hence, visual motion is potentially important in the perception of depth. Indeed, this belief has been developed and emphasized in "ecological" treatises (Gibson, 1966).

Evidence that motion parallax is effective comes from simulations: The observer rests his or her head on a movable chin support, while viewing monocularly an array of computer-generated dots. When the observer is stationary, the array appears as a single surface in the plane of the computer screen, as might be expected. However, moving the head generates simulated motion parallax in the array. Even minimal head motion elicits a compelling perception that the display consists of surfaces varying in distance from the observer (Rogers & Graham, 1982).

Does this conclusion apply to *real* stimuli—objects and surfaces truly varying in depth? As indicated above, real stimuli convey pictorial information based, for example, on their believed physical sizes and shapes. An Ames' "distorted-room" stimulus is rich in misleading pictorial information: It is constructed from trapezoidal surfaces slanted in depth to appear as the interior of a cube when viewed from a peephole in the front surface (Ittleson, 1952). Gehringer and Engel (1986) tested an assertion made by Gibson (1966) that the illusion is destroyed if the front surface is removed to permit head motion. In fact, motion had a much weaker effect in reducing the illusion than did binocular viewing, a result corroborated by research in which observers viewed single trapezoidal or triangular surfaces differing in their slant-in-depth (Reinhardt-Rutland, 1996).

How is the conflicting evidence from simulations and real stimuli to be reconciled? A first point is that visual motion is ambiguous: The moving observer may be viewing static objects, the static observer may be viewing moving objects, or the moving observer may be viewing moving objects (Reinhardt-Rutland, 1988). To resolve this ambiguity, effective motion parallax requires *cumulative* processing over time. In contrast, pictorial information is available for *immediate* processing, while binocular disparity relies on *simultaneous* comparison of the retinal images. Studies of real stimuli entail competition between motion and pictorial information; while motion parallax may have a role, rapid judgment is based on pictorial information. This even applies in a motion-rich activity such as driving, where depth judgments of child pedestrians or small automobiles may be wrong because pictorial information based on the sizes of "average" pedestrians and motor vehicles is applied inappropriately (Stewart, Cudworth, & Lishman, 1993).

Depth-from-motion simulations probably rely on the motion of the dots introducing information that is normally conveyed pictorially. An edge conveys the existence of two surfaces; the surface of one side of the edge is at a different distance than the surface of the other side of the edge. Edges are specified pictorially, even by something as simple as a line in a pen-and-ink drawing, but may also be defined by a spatial discontinuity in depth-from-motion simulations. Now an edge does not convey which surface is the closer; other information is required. Rogers and Rogers (1992) suggest that early depth-from-motion simulations had inadvertently included pictorial information in the display that allowed the observer to decide which parts of the array of dots appeared closer and which parts further away. When this pictorial information was eliminated, they found

that the depth relationships became ambiguous, confirming that dot motion may be restricted to specifying edges in simulations.

Another form of pictorial information, interposition, is enhanced by motion. For a moving observer, the pattern of interposition changes. At one point in the observer's motion, both objects may be fully visible. At another point, the more distant object may become partially or totally occluded. The changing pattern of occlusion varies systematically with the observer's motion, providing unambiguous information for relative order in depth (Gibson, 1966).

To conclude, motion parallax has a role in depth perception, but it is less important than some have asserted. Its limitation is that it requires time-consuming cumulative processing, while other sources of depth information are available for immediate processing. However, the observer's motion generates information that enhances pictorial information. It is this that may make the observer's motion important in depth perception.

MOTIVATED FORGETTING

All of us forget to remember, at least occasionally. Whether it is the name of a relative, an item to purchase at the store, or, more rarely, entire events from our lives, we have all experienced the phenomenon of forgetting. Unlike a digital camcorder, the human memory system does not encode and retrieve data in a mechanical fashion. Only a portion of what is available to our senses is stored in memory (long-term storage), and only a portion of what is stored is available at any given moment to be retrieved. Moreover, even when it is available for retrieval, not everything gets reported.

Sometimes, we forget because our old memories fade with the passage of time or are interfered with as new memories become stored. This is known as retroactive interference. Other times, we find it harder to remember more recent events and easier to remember our older memories because something interfered with the process of storing or retrieving these recent events; this is known as proactive interference. Both are unconscious forms of forgetting; that is, we are unable to recollect information despite energetic efforts to do so.

A less prosaic type of forgetting, however, is labeled "motivated," and it has nothing to do with the passage of time or interference from subsequent experiences. Many of the original ideas regarding "motivated forgetting" stem from Sigmund Freud, who stated that "besides the simple forgetting of proper names, there is another forgetting which is motivated by repression" (Freud, 1938, p. 40). According to Freud, this is particularly the case when dealing with memories of traumatic experiences. Since Freud, many writers and memory researchers frequently mixed these two types memory failure (repression and motivated forgetting) or used them interchangeably.

Some writers and researchers, however, distinguish between repression and motivated forgetting. For some, repression deals with the *unconscious* process of blockading potentially painful memories in order to protect the individual. Motivated forgetting, on the other hand, occurs when the individual *consciously* forgets about painful or embarrassing events (Thompson, Morton, & Fraser, 1997). Therefore, unlike the unconscious forms of forgetting and interference mentioned above, motivated forgetting has at its root a conscious desire to forget or "suppress" events. Unlike repression, where memories are claimed to be unavailable even if the individual tries very hard to recall them, motivated forgetting is associated with the ability to recall unpleasant experiences when we consciously attempt to do so. These memories are only temporarily out of consciousness as a result of a desire to avoid thinking of them.

Some make even finer distinctions within the concept of motivated forgetting. Wegner (1989), for example, proposes two more specific types of forgetting called "directed forgetting" and "thought suppression," both of which are similar to, yet distinct from, motivated forgetting. Although both directed forgetting and thought suppression are defined as "avoiding consciousness of a thought" (Wegner, 1989, p. 9), directed forgetting is used almost exclusively to refer to the forgetting of words. Thought suppression, however, is employed only when dealing with the forgetting of

discrete objects, events, or sequences of events, usually because the events are "too unpleasant, embarrassing, or threatening" (Ceci & Bruck, 1995, p. 194).

An example of thought suppression is to ask someone to try not to think of food when they are dieting. Ideally, they will actively engage in experiences that are distracting, such as watching TV or reading a book (Wegner, 1989). In the aftermath of a traumatic or embarrassing event, one might try to distract their thoughts away from this particular event and engage in thoughts about something more pleasant.

One irony about these types of forgetting (motivated, directed, and thought suppression) is that such monitoring techniques may increase the automatic activation of the thought that is supposed to be suppressed (Wegner, Quillian, and Houston, 1996). Therefore, by consciously trying to forget a word or event, one often becomes more likely to remember it, as demonstrated by the "try not to think of a pink elephant" phenomenon.

MOTIVATION

Motivation refers to the energizing states of animals and humans. Motivation leads to the instigation, persistence, energy or arousal, and direction of behavior. Motivation may involve biological survival, as in hunger or thirst, and it involves a wide range of learned processes. *Environmental cues* and *goals* are key in the study of motivation. Motivation may involve approach, such as seeking success on a task, or it may involve avoidance, such as seeking to avoid failure on a task. Many events are motivating, and motivation *disposition* differs from motivation *arousal.* One may become fearful or anxious as a motivational disposition, but this differs from being actually aroused, that is, *motivated,* in a given moment or situation.

Internal states of motivation, such as hunger, are experienced by species other than humans. However, some motivations appear to be uniquely human, such as the striving for excellence in achievement. Motivation plays a major role in psychodynamic theories of personality, like those of Alfred Adler and Sigmund Freud, and the literature in psychopathology addresses problems of disturbance in motivation, such as depression and anxiety. Many internal variables, including emotion, learning, cognition, problem solving, and information processing, are closely related to motivation, especially in the case of humans. Although these internal variables are interrelated, they are independently defined and scientifically investigated (Ferguson, 2000). Motivation has been studied in terms of social and cultural processes as well as from an evolutionary perspective.

Humans have many cognitive representations as goals, such as seeking new friends or striving to get a new job. Motivation, although influenced by external factors, refers to processes internal to the individual. Thus, others can set goals for an individual (Locke & Latham, 1990), as is done when a parent sets a standard for a child's school achievements or an employee's supervisor sets goals for work accomplishment. Often such an external goal is not motivating because the individual internally fails to self-set such a goal.

Intensity of Motivation

Motivation differs not only in kind, such as an individual's being thirsty rather than hungry, but also in intensity. One can be more or less thirsty, more or less hungry. Intensity may be described by a word such as *arousing,* which refers to the energizing aspect of motivation. The energizing effect of heightened motivation can be observed by means of physiological measures as well as by overt responses. Measures of brain waves, skin conductance, heart rate, and muscle tension can identify the intensity dimension of motivation. Under conditions of drowsiness and low excitation, electroencephalographic recordings generally show slow and large brain waves with a regular pattern, while under excited alertness the pattern is one of fast, low, irregular waves. When aroused or excited, individuals also tend to show an increase in muscle potential, as measured by electromyographic recordings, and a decrease in skin resistance. Individual differences lead to variation in physiological responses under arousal.

Animals generally run, turn wheels, and press bars at a faster rate when they have an increased level of motivation. For many species, including humans, heightened motivation tends to increase effort, persistence, responsiveness,

and alertness. Some contemporary theorists (e.g., Steriade, 1996) have found cortical desynchronization to be associated with the firing of specific neurons and with signs of behavioral arousal, but a full understanding of arousal processes is not yet available. Physiological, neurochemical, and psychological processes are involved in motivation. Motivation has been shown by health psychologists to affect immunological functioning (Cohen & Herbert, 1996), and in many ways, motivational states have a strong impact on the total health of the individual.

Complex Relationships Between Behavior and Motivation

One cannot infer the existence of a motivation merely by the presence of certain behaviors. For example, aggressive behavior does not presuppose a motivation or drive for aggression. Behavior is due to many factors. This complexity is illustrated by eating disorders such as obesity or bulimia, as well as in everyday life when people who are not food deprived nevertheless crave food when bored or anxious. Likewise, individuals can find food aversive and abstain from eating even when there is a strong tissue need for nourishment (Capaldi, 1996). People may eat when feeling unloved, and individuals may refrain from eating when motivated to seek social approval, obtain a job, or participate in a political hunger strike. Similarly, sexual behavior may occur when individuals seek power, prestige, or social approval rather than sexual gratification related to sexual arousal (McClelland, 1973). Although physiological needs may be powerful sources of motivation, they are neither necessary nor sufficient as the basis for motivation.

External rewards and reward pathways in the brain affect motivation and behavior, especially in addiction. Incentives of all types have been shown to affect motivation. For humans, intrinsic motivation that is internally generated differs from extrinsic motivation that is imposed by external sources (Deci, Kostner, & Ryan, 2001). Adlerian psychologists have found that children trained with encouragement and self-reliance rather than with praise and rewards are more likely to maintain socially constructive behaviors (Dreikurs, Grunwald, & Pepper, 1999; Dreikurs & Soltz, 2001).

Fear and Anxiety

Learning of all kinds, including early life experiences, shapes the way animals and humans respond to stressful and fear-arousing events. Different situations arouse motivation of fear and anxiety for different species and for different individual prior experiences. Stimuli associated with pain come to evoke fear, such that fear occurs when painful stimulation is anticipated. In humans, painful events are often symbolic and not merely physical, such as fear of failure (Atkinson, 1964).

Sigmund Freud postulated that human neurosis has its roots in anxiety. Clinical, field, and laboratory findings have demonstrated that defensive motivations like fear and anxiety are likely to lead to behaviors that interfere with effective task performance and creative problem solving. Task-oriented anxiety can be beneficial when the individual exerts effort toward task mastery, but self-oriented anxiety is likely to engender thoughts that indicate preoccupation with self-worth or personal safety, which interfere with problem solving and limit the amount of attention given to task demands. Fear of failure often leads to behaviors directed toward preventing failure rather than behaviors directed toward attaining success (Covington, 2000; Dweck, 1999).

Anxiety can be measured as both a trait and a state. Usually, but not always, the two show a strong positive correlation. In certain situations persons who have a disposition to be anxious (high trait anxiety) may have low state anxiety, and likewise, under specific circumstances persons of low trait anxiety may be very high in state anxiety. Anxiety can lead to stress-induced illness and lower immune system activity and is associated with lowered productive energy (Thayer, 1989). Memory, attentional control, and retrieval efficiency tend to suffer when an individual is anxious. High trait anxious people are more pessimistic and more prone to take note of threatening information than are persons with low anxiety (Eysenck, 1991).

Anxiety and fear in human beings can relate to actual threats but can also be self-generated. According to Adlerian theory and clinical evidence (Adler, 1927/1959; Dreikurs, 1967), emotions are linked with motivation. For example, a child may develop strong anxiety to get her parents to cater to her whims, or a husband may display marked anxiety as a means of getting his wife to pamper him and provide him service. The complexity of human motivation is well illustrated by anxiety, which can be facilitating as well as debilitating, can alter performance as well as be altered by it, and can serve a variety of interpersonal goals.

Anxiety tends not to lead to effective functioning. Rather, people function effectively when they believe positive outcomes are possible, and when they have self-confidence and confidence in others. When a person feels belonging, bonds with others, and contributes to the welfare of others, the individual functions effectively in many spheres of living. Contemporary writers have written about the need to belong, to feel competent, and to be self-determining, ideas that were formulated by Alfred Adler many decades ago (Adler, 1927/1959).

For humans, self-direction and symbolic processes are fundamental in determining motivation and its effects on behavior. Altruism and prosocial motivation enable humans to establish long-term emotional bonding, to overcome adversity, and to engage in cooperation and creative problem solving. Situational factors as well as intrinsic mo-

tivation shape people's cooperative or competitive actions and attitudes. Organismic and species variables are important in studying motivation in a wide range of animals. Additionally, for humans, societal and personal values, cultural and personal experiences, and many situational variables shape motivation and its effect on behavior.

MULTICULTURAL COUNSELING

Multicultural counseling assumes that each person's identity has been shaped by a great number of cultures and that effective counseling will address these different cultural identities in each client and community of clients. Multiculturalism has emerged as a social, political, economic, educational, and cultural movement during the last two decades. The term *multicultural* implies a wide range of special interest groups, without valuing any one of them as better or worse than others and without denying the distinct, complementary, or even contradictory perspectives that each group brings with it. Multicultural counseling recognizes that each of us belongs to many different cultures at the same time. Within-group differences as well as between-group differences are important in the multicultural perspective (Pedersen, 2000).

Interest in multicultural counseling grew out of the Civil Rights and feminist movements in the 1950s and the community mental health movement of the 1960s, which affirmed that mental health care was the right of all citizens. Popular dissent from the anti-Vietnam War movement and issues of feminism promoted discontent, while protest against inequity was accepted and encouraged by the media. By the 1970s, underuse of mental health services by minorities had become a serious issue. By the 1980s, large numbers of refugees further demonstrated the importance of a multicultural global perspective in counseling. By the 1990s, the rapidly changing demographic balance predicted that one third or more of the nation's school students would be non-White by the turn of the century. The war against terrorism since the year 2001 has further highlighted the lack of understanding among different cultures and countries.

Culture can be defined broadly or narrowly. Much research has contributed to and shaped the multicultural perspective for counseling, which initially was focused on the oppression of minorities by the majority culture. Culture has come to be defined more broadly to include special interest groups defined by ethnographic, demographic, status, and affiliation variables (Sue & Sue, 1999; Ponterotto, Casas, Suzuki, & Alexander, 2001; Pedersen, Draguns, Lonner, & Trimble, 2002).

Multiculturalism is becoming a "fourth force" to supplement the psychodynamic, behavioral, and humanist perspectives, emphasizing that all counseling takes place in a multicultural context (Pedersen, 1998). Behaviors are learned and displayed in a cultural context, so accurate assessment, meaningful understanding, and appropriate counseling intervention must also attend to that cultural context.

Multicultural counseling theory (MCT) (Sue, Ivey, & Pedersen, 1996) helps to clarify multiculturalism as a unified concept. MCT is based on six major propositions about counseling theories as worldviews which form the basis for

a multicultural metatheory. These propositions are: (1) each Western or non-Western theory represents a different worldview; (2) the interrelationships that clients and counselors experience in their cultural contexts must be the focus of counseling; (3) a counselor's or client's cultural identity will influence how problems are defined and dictate or define appropriate counseling goals or processes; (4) the ultimate goal of MCT is to expand the repertoire of helping responses available to counselors; (5) conventional roles of counseling are only some of many alternative helping roles available in other cultural contexts; and (6) MCT emphasizes the importance of expanding personal, family, group, and organizational consciousness in a contextual orientation.

There is also resistance to multiculturalism (Mio & Awakuni, 2000; Sue, 1998). Multiculturalism may be perceived as competing with established theories, and is associated with emotional issues of quotas and affirmative action. Multiculturalism is also connected with the postmodern movement. Some critics argue that the same unified counseling criteria should be applied to all cultures. The definition and standards for assessing multiculturalism have been challenged and the ideals of multiculturalism are judged by some to be impractical. Multiculturalism has also been associated with reverse racism and anti-White groups.

The multicultural movement in counseling has promoted research on racial and ethnic identity development. Ponterotto, Casas, Suzuki, and Alexander (2001) describe scales of ethnic identity for American Indians, Blacks, Hispanics, Whites, and other populations that generally include five stages. The first "pre-encounter" stage is the level of least awareness. In the second "encounter" stage, a crisis occurs, followed by a third "immersion-emersion" stage in which cultural identity becomes more explicit. In the fourth "internalization" stage these new insights are internalized. The fifth and final "internalization-commitment" stage represents the highest level of racial/ethnic awareness. These categories of progressive awareness are important for counselors to use in assessing their own competency, as well as for defining constructive growth among clients from different cultural backgrounds.

Members of the APA's Division 17 (Counseling) Education and Training Committee developed a position paper of competencies for multicultural counseling (Sue et al., 1982). These competencies emphasize awareness, knowledge, and skill in a developmental sequence. These competencies have been updated in Sue et al., (1998) and other publications.

The awareness competencies describe the need for counselors to become cognizant of their own cultural heritage while valuing and respecting differences, to be aware of how their own values may affect culturally different clients, to become comfortable with differences in race and belief between clients and counselors, and to know when a minority client should be referred elsewhere.

The knowledge competencies describe the need to have a good understanding of the sociopolitical dynamics between minority and majority cultures, to have specific knowledge and information about the client's particular culture, to have a clear and explicit knowledge of generic and traditional counseling theory and practice, and to be aware of institutional barriers that prevent minorities from using mental health services.

The skill competencies assume that all culturally skilled counselors will be able to generate a wide variety of verbal and nonverbal responses appropriate to the cultural setting and skill level, that counselors will be able to accurately send and receive both verbal and nonverbal messages in each culturally different context, and that counselors will be able to advocate for change within the system or institution appropriately, when changes are necessary, on behalf of their culturally different clients.

These competencies have been adopted by the American Psychological Association as well as the American Counseling Association for professional standards of counseling (Sue et al., 1998).

MULTIMODAL THERAPY

Multimodal therapy (MMT) provides an integrative assessment and treatment plan that considers the whole person in his or her social network. Multimodal therapy places most of its theoretical underpinnings within a broad-based social and cognitive learning theory, but draws on effective techniques from many disciplines without necessarily subscribing to their particular suppositions (i.e., it espouses technical eclecticism). In MMT one endeavors to use, whenever possible and applicable, empirically supported methods. Thus, its practitioners are at the cutting edge of the field, drawing on scientific and clinical findings from all credible sources.

This technically eclectic outlook is central and pivotal to MMT. It is important to understand that the MMT approach sees *theoretical* eclecticism, or any attempt to integrate different theories in the hopes of producing a more robust technique, as futile and misguided (see Lazarus, 1992, 1997).

Multimodal therapy is predicated on the assumptions that most psychological problems are multifaceted, multidetermined, and multilayered, and that comprehensive therapy calls for a careful assessment of seven parameters or modalities—Behavior, Affect, Sensation, Imagery, Cognition, Interpersonal relationships, and Biological processes. The most common biological intervention is the use of psychotropic Drugs. The first letters from the seven modalities yield the convenient acronym BASIC I.D.—although it must be remembered that the "D" represents not only the drugs commonly used for biological intervention, but the entire panoply of medical and biological factors.

It is assumed that the more a patient learns in therapy, the less likely he or she is to relapse. In other words, therapeutic breadth is emphasized. Over many years, my follow-ups have revealed more durable treatment outcomes when the entire BASIC I.D. is assessed, and when significant problems in each modality are remedied. Multimodal therapy uses several distinct assessment procedures that tend to facilitate treatment outcomes.

Second-order BASIC I.D. assessments may be conducted when therapy falters. For example, an unassertive person who is not responding to the usual social skills and assertiveness training methods may be asked to spell out the specific consequences that an assertive modus vivendi might have on his or her behaviors, affective reactions, sensory responses, imagery, and cognitive processes. The interpersonal repercussions would also be examined, and if relevant, biological factors would be determined (e.g., "If I start expressing my feelings I may become less anxious and require fewer tranquilizers"). Quite often, this procedure brings to light reasons behind such factors as noncompliance and poor progress. A typical case in point concerns a man who was not responding to role-playing and other assertiveness training procedures. During a second-order BASIC I.D. assessment, he revealed a central cognitive schemata to the effect that he was not entitled to be confident, positive, and in better control of his life, because these qualities would show up his profoundly reticent and inadequate father. Consequently, the treatment focus shifted to a thorough examination of his entitlements.

A 35-item *Structural Profile Inventory* (SPI) yields a quantitative BASIC I.D. diagram depicting a person's degree of activity, emotionality, sensory awareness, imagery potential, cognitive propensities, interpersonal leanings, and biological considerations (see Lazarus, 1997). The SPI is particularly useful in couples therapy where differences in the specific ratings reflect potential areas of friction. Discussion of these disparities with clients can result in constructive steps to understand and remedy them.

A method called *tracking* may be employed when clients are puzzled by affective reactions. "I don't know why I feel this way." "I don't know where these feelings are coming from." The client is asked to recount the latest untoward event or incident. He or she is then asked to consider what behaviors, affective responses, images, sensations, and cognitions come to mind.

One client who reported having panic attacks for no apparent reason was able to put together the following string of events. She had initially become aware that her heart was beating faster than usual. This brought to mind an episode in which she had passed out after drinking too much alcohol at a party. This memory or image still occasioned a strong sense of shame. She started thinking that she was going to pass out again, and as she dwelled on her sensations, the cognition only intensified, culminating in her feelings of panic. Thus, she exhibited an S-I-C-S-C-A pattern (Sensation, Imagery, Cognition, Sensation, Cognition, Affect). Thereafter, she was asked to note carefully whether any subsequent anxiety or panic attacks followed what might be called a similar firing order. She subsequently confirmed that her two trigger points were usually sensation and imagery. This alerted the therapist to focus on sensory training techniques (e.g., diaphragmatic breathing and deep muscle relaxation) followed immediately by imagery training (e.g., the use of coping imagery and the selection of mental pictures that evoked profound feelings of calm).

The BASIC I.D. lends itself to other assessment and treatment tactics that keep the clinician on track and enable him or her to address issues that might otherwise have been glossed over. Lazarus (1997) presents these methods in some detail.

Research findings on overall effectiveness of MMT have been conducted by Kwee (1984), a Dutch psychologist, who obtained encouraging results when conducting a controlled-outcome study using MMT with severe obsessive-compulsive patients, and with a group of extremely phobic individuals. Williams (1988), a Scottish psychologist, in a careful controlled-outcome study, compared MMT with other treatments in helping children with learning disabilities. He

emerged with clear data pointing to the efficacy of MMT in comparison to the other methods studied.

In essence, it should be understood that MMT is a broad-spectrum orientation, extremely flexible, with which the therapist may match the best and most effective methods with the appropriate treatment style for each individual. It is both brief and comprehensive (Lazarus, 1997).

MULTIPLE CORRELATION

Multiple correlation is a multivariate analysis method widely used in psychology and other behavioral sciences. It can be considered an extension of bivariate correlation, and indicates the degree of association between one variable and an optimally weighted combination of several other variables. The weights are determined by the principle of least squares so as to minimize the residual, or unrelated, variance.

The multiple correlation ranges in value from zero to one, and is interpreted similarly to a bivariate correlation, if rectilinearity and the other assumptions of the bivariate intercorrelations from which the multiple correlation is computed are reasonable.

In psychology the squared multiple correlation (R^2) frequently is used to estimate the proportion of variance in a dependent variable that is related to a set of independent variables. A related method, multiple regression, is used for predicting a dependent (or criterion) variable from a set of independent (or predictor) variables.

Benjamin Fruchter

See also: **Correlation Methods; Multiple Regression**

MULTIPLE REGRESSION

Multiple regression is a multivariate analysis method that relates a dependent (or criterion) variable (Y) to a set of independent (or predictor) variables (X) by a linear equation.

$$Y' = a + b_1X_1 + b_2X_2 + \ldots + b_kX_k$$

The regression or b weights are usually determined by the principle of least squares, to minimize the sum of the squared deviations of the dependent values from the corresponding predicted values.

In a "stepwise" approach, variables are added (or removed) one at a time from the independent variable set until there is a nonsignificant change. Also, sets of variables may be added (or removed) to evaluate their contribution to the multiple correlation, and an F-test done to determine if their effect is statistically significant. Nonlinear relationships may be evaluated by including higher order terms and/or multiplicative terms on the right-hand side of the equation.

The regression weights are determined most reliably when the independent variables are relatively uncorrelated. The situation in which some of them are highly intercorrelated is "multicollinearity," and tends to yield regression coefficients whose values may fluctuate markedly from sample to sample. Some common uses for multiple regression are

1. To obtain the best linear prediction equation
2. To control for confounding variables
3. To evaluate the contribution of a specific set of variables
4. To account for seemingly complex multivariate interrelationships
5. To perform analysis of variance and covariance by coding the levels of the independent variables

MULTISYSTEMIC THERAPY

General Description

Multisystemic therapy (MST), developed and refined by Scott Henggeler and his colleagues over the past 25 years, is an intensive family- and community-based treatment for youth presenting with serious clinical problems (e.g., antisocial behavior, substance abuse, emotional disturbance) that focuses on changing the empirically derived determi-

nants of these problems within a broad-based, social ecological framework. MST uses evidence-based interventions designed to attenuate known risk factors and to enhance protective factors at multiple levels of the youth's social ecology. These levels include characteristics of individuals, salient features of encapsulating social environments (e.g., families, schools, peer groups, etc.), and the relations between and among individuals and their relevant social settings (e.g., caregiver-teacher relationships, family-school linkages).

Core Principles

MST therapists are guided by nine core principles that direct them: (1) to assess the fit between identified problems and their broader systemic context; (2) to emphasize the positive and use systemic strengths as levers for change; (3) to promote responsible and decrease irresponsible behavior among family members; (4) to implement present-focused and action-oriented interventions aimed at specific and well-defined problems; (5) to target sequences of behavior within and between multiple systems that maintain the identified problems; (6) to design interventions that fit the developmental needs of the youth; (7) to require daily or weekly effort by family members; (8) to evaluate intervention effectiveness continuously from multiple perspectives with providers assuming responsibility for overcoming barriers to successful outcomes; and (9) to promote generalization of therapeutic change by empowering caregivers to address family members' needs across multiple systemic contexts.

Theoretical Underpinnings

Four theories/perspectives have been especially influential in the formulation of MST (1) *social ecological perspectives* articulating that human development is multiply determined by complex interdependencies of individuals and the nested social environments (families, schools, peer groups, neighborhoods) in which they are immersed; (2) *family systems theories* emphasizing that maladaptive behaviors of youth stem from faulty family communication/problem solving processes and problematic family structures (e.g., cross-generation alliances, inadequate levels of cohesion or adaptability); (3) *social learning / behavioral theories* specifying that externalizing behaviors are learned and maintained because they "pay off" in terms of either positive or negative reinforcement (e.g., achievement of specific resources, escape or avoidance of unwanted outcomes) delivered contingently by caregivers and peers; and (4) *structural-organizational* and *resilience* perspectives emphasizing the importance of protective factors (e.g., strengths of individuals, families, and social systems) in counteracting or buffering negative effects of risk factors, thus potentially yielding relatively adaptive outcomes for high-risk youth and their families.

Empirical Foundations

The aforementioned theories/perspectives have driven a substantial body of empirical research that, in turn, has elucidated the determinants of serious problem behaviors in youth. The malleable determinants have become targets for change in MST intervention programs. Two major types of research have influenced MST interventions and its theory of change: (1) multivariate cross-sectional and passive (nonintervention) longitudinal studies that delineate the correlates/predictors of youth behavioral and emotional problems, and (2) treatment outcome studies that target theory-driven risk/protective factors and yield beneficial results for high-risk youth. For example, both types of research support a social ecological perspective, a central guiding feature of MST. Numerous nonintervention studies indicate that challenging clinical problems of youth are determined by multiple factors at multiple levels of analysis. In addition, treatment outcome studies using ecologically oriented interventions have demonstrated effectiveness in reducing antisocial behavior in adolescents.

Intervention Strategies, Service Delivery, and Treatment Fidelity

Specific MST interventions include strategies from pragmatic family therapies, behavioral parent training, social learning/contingency management approaches, and cognitive-behavioral therapy. Interventions are theory-based, have empirical support, and are delivered strategically and flexibly throughout the treatment process. MST interventions often have the following goals: (1) to reduce unproductive caregiver-youth conflict; (2) to improve caregiver monitoring, limit setting, and family management practices; (3) to enhance family communication and problem-solving mechanisms; (4) to develop adaptive levels of family cohesion and adaptability; (5) to extricate youth from ties with deviant peers and to increase their association with prosocial peers; (6) to increase academic and social competencies; and (7) to increase involvement with prosocial organizations (e.g., religious groups, community recreational facilities).

MST therapists have low caseloads (i.e., four to six families), provide treatment in natural environments (i.e., home, school, and neighborhood settings), schedule sessions at convenient times for families (e.g., evenings and weekends), and maintain availability for interventions 24 hours per day and 7 days per week. Treatment involves approximately 60 hours of direct service extending over 3 to 6 months (and thus is time-limited). These practices likely contribute to the high treatment completion rates evidenced across MST studies.

MST includes comprehensive and continuous quality assurance mechanisms designed to maximize treatment fidelity (e.g., manualization of clinical, supervisory, consul-

tative, and administrative procedures; provision of weekly feedback to therapists from clinical supervisors and MST consultants). Clinical training and supervision focus on therapist adherence to the core MST principles. Adherence scores on a standardized questionnaire completed by caregivers have been associated with positive youth and family outcomes. Empirical support for MST quality assurance mechanisms has been obtained and should facilitate the effective transport of MST nationally and internationally.

Effectiveness Trials

Multiple published outcome studies (including seven randomized clinical trials), and the preliminary results of investigations in progress suggest that MST is an effective treatment for antisocial youth (including substance use problems). MST also shows promise for treating youth experiencing psychiatric emergencies, juvenile sexual offenders, and maltreated children. Evidence regarding the relative cost effectiveness of MST in comparison with traditional services is also encouraging. MST studies have met stringent standards of methodological rigor consistent with high internal validity, and have been conducted in community settings with heterogeneous client populations (using few exclusion criteria), thus bolstering the external validity of results.

Treatment outcome studies consistently have found differences in favor of MST on putative mediators of change (e.g., improved parent-child relationships) as well as ultimate outcomes (e.g., reduced criminal behavior). More recently, mediational analyses conducted on two independent samples of antisocial youth corroborated key features of the theory of change underlying MST. MST improved parenting and global family functioning and reduced youth association with deviant peers; these changes, in turn, were associated with reductions in criminal activity.

MYELINATION

The functional unit of the nervous system, the neuron, is equipped with a specialized region for transmitting information called the axon. The speed at which a neuron can convey sensory information to the brain and motor information to the muscles is dependent upon two critical features of its axon: its diameter and the presence of a myelin sheath. By increasing the diameter of an axon, a strategy used in the nervous system of both invertebrates and vertebrates, the conduction velocity of a fiber increases as a result of a lower axolemma resistance to the flow of current.

However, the limits to which the brain can expand in size as a result of this adaptation has prompted a second strategy to evolve that increases the speed of action potential propagation with little axon diameter growth (Hildebrand, Remahl, Persson, & Bjartmer, 1993). This strategy, called myelination, results from a complex interaction between neurons and oligodendrocytes in the central nervous system (CNS) or Schwann cells in the peripheral nervous system (PNS). These two glial cell types are capable of synthesizing a membrane structure, called myelin, which is elaborated into a sheath and wrapped, in a concentric fashion, around an axon (Figure 1).

This sheath of myelin is not continuous along the length of an axon but is laid down as segments of myelin (internodes) that are interrupted, at regular intervals, by areas devoid of myelin. These regions are termed the nodes of Ranvier (Figure 2). Moreover, sodium channels are concentrated at these nodes but virtually absent from regions of axon membrane covered by a myelin sheath. Therefore, when an action potential is triggered, the insulating properties of the myelin sheath and the enrichment of sodium channels at the nodes allows current to be swiftly funneled by passive spread to the next node. This movement of the action potential from node to node is termed *saltatory con-*

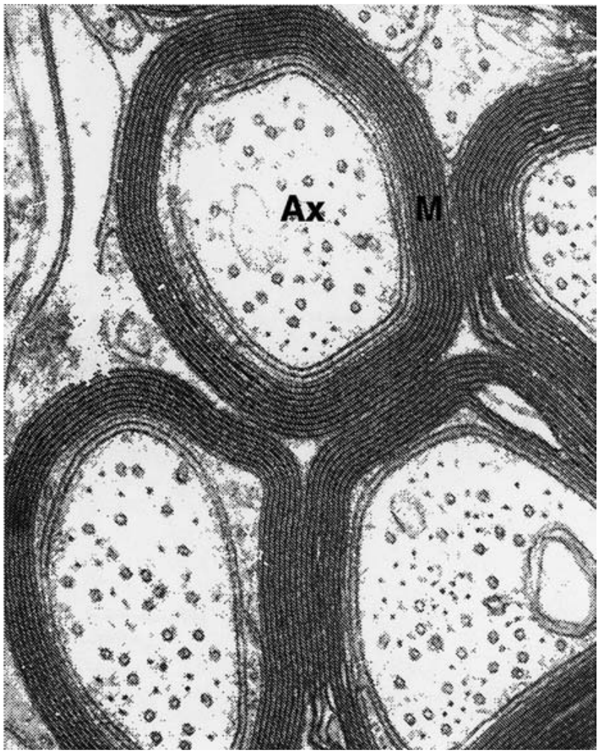

Figure 1. Electron micrograph showing central nervous system axons (Ax) ensheathed with myelin (M) produced by oligodendrocytes.

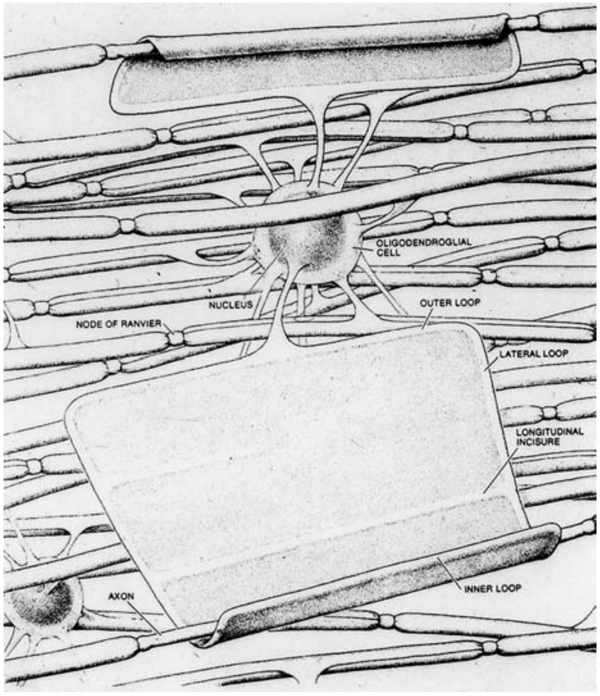

Figure 2. Illustration of an oligodendrocyte ensheathing multiple axons with internodes of myelin.

duction and enables myelinated axons with a diameter of 4μm to convey information at the same speed as unmyelinated axons with a diameter of 500μm. Therefore, axon myelination provides the means by which the nervous system can convey electrical impulses at high speeds in a confined manner. Conversely, any loss of axon myelination, as seen in demyelinating diseases or nervous system trauma, disrupts action potential propagation, resulting in devastating consequences to normal motor and sensory functions (Compston, Scolding, Wren, & Noble, 1991).

Although the interactions that occur between neurons and either Schwann cells or oligodendrocytes produce the same outcome, that is, an axon ensheathed in myelin, myelination in the peripheral and central nervous systems differ in a number of ways (Colello & Pott, 1997). In particular, it has been estimated that a single oligodendrocyte can ensheath 20 to 50 axons with an internode of myelin, whereas, a single Schwann cell will ensheath only one axon with myelin. Consequently, the destruction of one oligodendrocyte will have a larger impact on motor or sensory function than the destruction of one Schwann cell. Moreover, it has been shown that myelin produced from oligodendrocytes and Schwann cells differs to some degree in its biochemical makeup of lipids and proteins (Snipes & Suter, 1995; Campagnoni, 1998). This may explain why some myelin diseases target preferentially either the central or peripheral nervous system. Regardless of differences, myelination in both systems can be regarded as the culmination of events that began with the differentiation of glial cells from mitotically active, migratory precursor cells. Upon becoming postmitotic, these cells proceed to transcribe and translate the genes that make up myelin. The elaboration of myelin into a sheath by the processes of glial cells and the subsequent recognition of target axons are further distinct steps along the pathway leading to myelination. Finally, the initiation of axon ensheathment and the subsequent compaction of the myelin sheath around the axon completes the stages of myelination.

Although the process of myelination enables axons to propagate action potentials quickly and in a compact manner, the complexity of this neuron/glia interaction results in an increased vulnerability of the nervous system to disease. Indeed, there are a large number of identified pathological conditions that primarily target myelin (Hopkins, 1993). These diseases, which can lead to the destruction of the myelin sheath, are categorized as either acquired (i.e., multiple sclerosis) or hereditary diseases (i.e., leukodystrophies). Multiple sclerosis, which is the most common human demyelinating disease, is characterized by the formation of plaques, or areas of demyelinated axons that can develop virtually anywhere in the central nervous system (Figure 3). Although axons can be spared in the plaque regions and remyelinate during periods of disease remission, cumulative axonal loss is thought to provide the pathologic substrate for the progressive disability that most long-term MS patients experience (Bjartmar & Trapp, 2001). These findings suggest that any therapeutic treatment aimed at restoring function in patients with demyelinating disease will need to combine both remyelinating and neuroprotective strategies. Further complicating such therapeutic attempts, however, is the observation that myelin debris, known to be present within demyelinating lesions, includes factors inhibitory for neuronal regeneration after central nervous system injury (Schwab, 2002). Fortunately, the re-

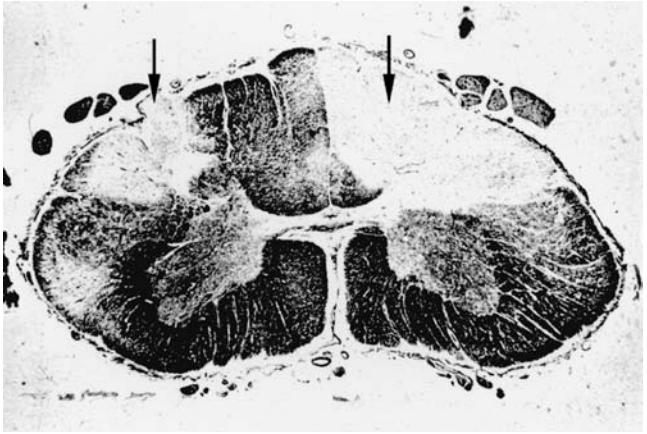

Figure 3. Cross-section of the spinal cord of a patient who had multiple sclerosis showing the loss of myelin (black stain) in fiber tracts of the spinal cord (arrows) responsible for conveying sensory impulses and voluntary movement.

cent identification of receptor molecules with redundant binding activities for such inhibitory factors (Domeniconi et al., 2002; Liu, Fournier, GrandPre, & Strittmatter, 2002) should allow for the development of additional strategies aimed at repairing neurons that have undergone demyelination.

NARCOLEPSY

Narcolepsy is a lifelong neurological disorder of rapid eye movement (REM) sleep in which the affected individual has attacks of irresistible daytime sleepiness, cataplexy (sudden muscle weakness in response to emotional triggers like surprise, laughter, fright, or anger), hypnagogic hallucinations (vivid and often terrifying dreams at sleep onset), and sleep paralysis (a momentary inability to move as one is drifting off to sleep). Cataplexy, hypnagogic hallucinations, and sleep paralysis are all manifestations of intrusion of REM sleep onto wakefulness. The entire constellation of symptoms may not be present initially, but appears gradually over a period of 5 to 10 years. Daytime sleepiness and cataplexy are the two most reliable features of narcolepsy. The daytime sleepiness frequently leads to automatic behavior of which the subject is unaware, impairment of memory, concentration, and executive function as well as mood swings. Nighttime sleep is also disturbed, with frequent awakenings, with or without associated periodic limb movements in sleep.

The incidence of narcolepsy in United States is 1.37 per 100,000 persons per year (1.72 for men and 1.05 for women). It is highest in the second decade, followed by a gradual decline thereafter. The prevalence rate is approximately 56 persons per 100,000 persons (Silber, Krahn, Olson, & Pankrantz, 2002). A meta-analysis of 235 subjects derived from three studies found that 34% of all subjects had onset of symptoms prior to age 15, 16% prior to age 10, and 4.5% prior to age 5 (Challamel et al., 1994). Patients frequently report a lag of 5 to 10 years between the onset of clinical symptoms and establishment of the definitive diagnosis, suggesting insufficient awareness of the disorder among health professionals.

Narcolepsy has been described in miniature horses, Brahmin bulls, quarter horses, and about 15 breeds of dogs. Canine narcolepsy has autosomal recessive inheritance, and is related to a deficiency of hypocretin 2 receptors. On the other hand, the murine model of narcolepsy is associated with deficiency of the hypocretin (orexin) ligand. Hypocretin is a peptide that is elaborated in dorsomedial and dorsolateral areas of the hypothalamus. Hypocretin-containing neurons have widespread projections to the forebrain and brain stem. Activation of hypocretin projections leads to up-regulation of arousal mechanisms, increased muscle tone, muscle activity, and metabolic rate.

Human narcolepsy-cataplexy is associated with a marked deficiency hypocretin–1 in the cerebrospinal fluid. In contrast to the autosomal recessive transmission of canine narcolepsy, the pathogenesis of human narcolepsy is more complex, and appears to be related to an interplay between genetic and environmental factors. The histocompatibility antigen DQB1*0602 is present in 90 to 95% of patients with narcolepsy, in contrast to a 25 to 30% prevalence in the general population. Genetic susceptibility per se is, however, insufficient to trigger symptoms, as evidenced by the fact that monozygotic twins may be discordant for the disorder. Environmental stresses like head trauma, systemic infection, or surgery precede the development of clinical symptoms in two thirds of subjects, thus supporting a "two-hit" hypothesis. Rare instances of *secondary narcolepsy* following encephalitis, hypothalamic tumors, central nervous system lymphoma, and vascular malformations also suggest a contribution from acquired factors. It is presumed that low central nervous system levels of hypocretin–1 decrease noradrenergic activity and also lead to disinhibition of the brain stem cholinergic systems, thus triggering both sleepiness and cataplexy.

The diagnosis of narcolepsy is established on the basis of the narcoleptic tetrad (overwhelming sleepiness, cataplexy, hypnagogic hallucinations, sleep paralysis), combined with characteristic findings on the nocturnal polysomnogram and the multiple sleep latency test (MSLT). The nocturnal polysomnogram is a procedure in which the activity of multiple bodily functions, such as the electroencephalogram (EEG), eye movements, chin and leg electromyogram (EMG), airflow, thoracic and abdominal respiratory effort, electrocardiogram, and oxygen saturation, are recorded simultaneously on a strip of moving graph paper or a computer system. The test helps exclude disorders such as obstructive sleep apnea and periodic limb movement disorder which may also impair daytime alertness and mimic narcolepsy. On the morning following the nocturnal polysomnogram, the patient undergoes the MSLT, during which four 20-minute nap opportunities are provided at two hourly intervals in a darkened, quiet room (e.g., at 1000, 1200, 1400, and 1600 hours). The speed with which the subject falls asleep is measured using the EEG, chin EMG, and eye movement recordings. The time between "lights out" and sleep onset is termed the *sleep latency.* The mean sleep latency is calculated by adding the sleep latencies of individual naps and dividing by the total number of naps. The

mean sleep latency is markedly shortened to less than 5 minutes in subjects with narcolepsy, as compared to normal values in the 14 to 20 minute range in unaffected controls. Furthermore, unaffected individuals show a transition from wakefulness into REM sleep, while patients with narcolepsy tend to shift from wakefulness directly into REM sleep.

The differential diagnosis of narcolepsy includes insufficient sleep, abnormal sleep hygiene, circadian rhythm disorders like the delayed sleep phase syndrome, the upper airway resistance syndrome, idiopathic hypersomnia, depression, periodic hypersomnia, and abuse of hypnotic/sedative drugs (prescription or over-the-counter).

Narcolepsy requires lifelong treatment. Daytime sleepiness is countered with stimulants like methylphenidate or dextroamphetamine. The side effects include anorexia, nervousness, tics, and insomnia. Modafinil (Provigil), a drug with an unspecified mode of action, is also effective in enhancing alertness and improving psychomotor performance. Gamma hydroxybutyrate also holds promise as an agent for both enhancing alertness and reducing cataplexy. Because cholinergic pathways in the brain stem mediate cataplexy, drugs such as clomimipramine and protryptiline with anticholinergic properties have been used to treat cataplexy. Replacement therapy with hypocretin analogues holds some long-term promise. One to three planned naps per day, each lasting 25 to 30 minutes, are also helpful in enhancing alertness. Supportive psychotherapy and fluoxetine may be needed if the patient develops emotional or behavioral problems.

Because of the increased risk of accidents from sleepiness, patients with narcolepsy should be cautioned against driving and should not work close to sharp, moving machinery. The Narcolepsy Network, Inc. (http://www.narcolepsynetwork.org) is a helpful nonprofit patient support organization.

NATIONAL INSTITUTE OF MENTAL HEALTH

The National Institute of Mental Health (NIMH), a component of the U.S. National Institutes of Health (NIH), supports and conducts research to reduce the burden of mental and behavioral disorders through a better understanding of mind, brain, and behavior. In the United States, mental disorders collectively account for more than 15 percent of the overall burden of disease, a term that encompasses both premature death and disability associated with illness. The NIMH is the nation's largest single source of support for research on mental disorders, with an appropriated budget of $1.25 billion in fiscal year 2002. Approximately 85% of this budget supports research grants and contracts at universities, hospitals, and other settings throughout the country. The Institute also administers an intramural, or in-house, research program that accounts for about 11% of its budget.

Creation and Early History of NIMH

Although the origins of NIMH can be traced to the federal government's efforts to provide treatment to narcotic addicts in the early twentieth century, more immediate impetus for the Institute's creation was the fact that psychiatric disorders were found to be the largest cause for medical discharges from the military during WWII and accounted for nearly 40% of Selective Service rejections. When these data stimulated congressional interest, Robert Felix, M.D., then director of the U.S. Public Health Service's Division of Mental Hygiene, expanded an earlier proposal to create a federal neuropsychiatric research institute to encompass responsibility for developing the nation's supply of mental health clinical personnel and assisting states to expand community-based mental health treatment facilities. This proposal received a prompt and positive hearing by Congress, which passed the National Mental Health Act (P.L. 79-487) that was signed into law by President Truman on July 3, 1946.

Upon its establishment, NIMH consisted of three extramural funding units focused, respectively, on research grants and fellowships, clinical training, and community services, and the fledgling intramural research program. Research opportunities in the biological, behavioral, and social sciences encouraged steady growth in basic and clin-

ical research; NIMH also invested heavily in training scientists. With respect to developing a national pool of mental health clinicians, stipends to trainees and funding of faculty salaries were the most common means of support, although NIMH strove to accommodate specific needs of various disciplines, funding curriculum development conferences and visiting teacherships in psychology, for example, and funding career teacher and career investigator awards needed to develop mental health research capacity. In the mental health services arena, NIMH worked with states to develop community-based mental health services, stimulating an initiative that grew dramatically after President Kennedy signed a 1963 law authorizing NIMH to fund a national network of community mental health centers (CMHCs) that were anticipated to reduce need for long and costly hospitalization. Key CMHC concepts were early identification and prevention of mental disorders; provision of a comprehensive array of services; and continuity of care.

Over the years, scientific progress and opportunities, public health needs, and political directives have influenced NIMH's research priorities. In 1965, for example, President Johnson pledged to ensure the relevance of federally funded research to social ailments. NIMH responded by creating problem-focused centers to insure that basic and applied research, training, service demonstrations, and related activities would be devoted to critical targets. Centers were created to focus on Schizophrenia and suicide, but also on crime and delinquency, urban mental health, alcohol and drug abuse, minority group mental health, and, under congressional mandate, the prevention and control of rape. In 1970, award of the Nobel Prize to NIMH scientist Julius Axelrod for his studies of neurochemical processes in the brain signaled growing emphasis on research into basic biological and behavioral substrates of mental disorders.

Still, the Institute's involvement in mental health services and its high-profile role in social problems research clearly differentiated it from other NIH components, and in 1967 the NIMH was separated from the NIH. Six years later, the NIMH centers focusing on alcohol and drug abuse were converted to full-fledged institutes, and a new agency, the Alcohol, Drug Abuse, and Mental Health Administration, was created to serve as an umbrella for the three institutes.

By the late 1970s, NIMH's investment in CMHCs had helped transform the mental health care system into a pluralistic system comprising federal, state, local, and private facilities. Deinstitutionalization of long-term residential mental hospitals that had begun with the introduction of effective psychotropic drugs in the 1950s accelerated with the advent of federal reimbursement programs that underwrote services traditionally funded by states. In order to more effectively target services to persons with severe mental illnesses, the NIMH launched in 1977 a pilot Community Support Program (CSP) designed to assist states and communities improve mental health and related support services for adults with chronically disabling mental health problems. The success of the CSP in reducing need for hospitalization came to be widely recognized, and most states invested additional money to complement the start-up investment made by NIMH.

Through the 1970s and 1980s, NIMH refocused mental health clinical training on special areas such as children, the elderly, minorities, and the chronically mentally ill, and on mental health consultation/liaison, given the increasing role of the general medical sector in providing mental health care. By the time NIMH was relieved of clinical training authority in 1992, annual funding for these programs had dwindled to $13 million, from a high point of $98 million in 1969.

In the late 1970s, competition between NIMH research and service priorities was being questioned sharply by many people. NIMH increased its research investment in neuroscience and related brain and behavior research; clinical treatment studies; epidemiology; and an area of emerging interest, mental health services/economics research. Support for this shift and for an intended refocusing of service programs on treatment needs posed by severe mental illness received added impetus in the late 1970s with the emergence of a vocal mental health consumer movement. The National Alliance for the Mentally Ill (NAMI) and, subsequently, the National Depressive and Manic Depressive Association (NDMDA) and the Anxiety Disorders Association of America (ADAA), were key consumers' groups that added an authentic and compelling note of urgency to an advocacy effort that had been borne for many years by the National Mental Health Association.

The shift toward research as the defining mission of the NIMH that occurred during the 1980s was punctuated in 1989 when President George Bush signed into law (P.L. 101-58) a presidential proclamation designating the 1990s the "Decade of the Brain," and again in 1992 when advocacy groups favoring closer ties of mental health science and practice to mainstream medicine supported a reorganization that reunited NIMH's research and research training with the NIH while assigning service responsibilities to a new federal agency. Today, NIMH is exclusively a research institute with four broad scientific priorities: basic research in molecular biology, neuroscience, genetics, and behavior; the translation of new basic knowledge into clinical applications; treatment effectiveness studies that will provide a foundation for evidence-based practice; and research dissemination activities.

Richard K. Nakamura
National Institute of Mental Health

NATIONAL INSTITUTES OF HEALTH

The National Institutes of Health (NIH) is the U.S. federal government's principal agency for the support of medical

research. The mission of the NIH is to uncover new knowledge that will lead to improved human health. With a 2001 budget of more than $20 billion, the 27 institutes and centers that comprise the NIH award about 84 percent of the money through a grants program to investigators in universities and other institutions across the United States and to some foreign researchers. A smaller in-house program of research so-called intramural research, is funded on the NIH's campus in Bethesda, Maryland, and ancillary sites.

This present-day configuration emerged after World War II, but the NIH itself traces its roots to 1887, when a one-room bacteriological laboratory was created within the Marine Hospital Service, predecessor agency to the U.S. Public Health Service. Initially, infectious diseases were the primary concern of the laboratory. Beginning in 1902, research expanded into the areas of pharmacology, chemistry, and zoology, and after 1912, research into noncontagious diseases was also included. Basic research, especially in chemistry, became an interest of laboratory scientists in the 1920s and 1930s. In 1937, the first categorical institute, the National Cancer Institute (NCI), was created as a separate entity from the NIH.

During World War II, all NIH research was redirected toward the war effort. In 1944, a Public Health Service reorganization act introduced two features that shaped the subsequent development of the modern NIH. First, the NIH was permitted to award grants in aid of research; second, the NIH was permitted to conduct clinical research. Health-related lobbying groups also convinced Congress to create additional categorical institutes, the first of which was the National Institute of Mental Health (NIMH), authorized in 1946. By 1948, institutes for heart disease and dental research joined existing programs in microbiology and experimental biology and medicine to bring the number of institutes to six.

Other institutes investigated arthritis, eye diseases, neurological diseases, deafness, and diabetes, among other diseases. The National Library of Medicine (NLM) developed bioinformatics, and the Fogarty International Center coordinated international biomedical research activities. In addition to disease-focused components, institutes for research on the broad areas of child health, aging, nursing, and general medical sciences were also added. In recent years, components for human genome research, complementary and alternative medicine, biomedical imaging and bioengineering, and several others have come into the NIH. In 2002, 27 institutes and centers sponsored multiple research initiatives related to their categorical missions. In addition, trans-NIH initiatives seek to coordinate work across institute boundaries. Special disciplinary interest groups, a bioengineering consortium, and a mammalian gene collection reflect other cross-cutting efforts.

In the 1950s, research in psychology and the neurosciences, although technically housed in two separate institutes, shared a common in-house research program. The most highly recognized research growing out of this effort was Julius Axelrod's work on the reuptake phenomenon of neurotransmitters, for which he won a 1970 Nobel prize in "medicine or physiology." Axelrod's work, which built on a biological foundation for mental health research that had begun with the psychopharmacology revolution of the 1950s and 1960s, punctuated the ascendancy of neuroscience research at NIMH as well as at the National Institute on Neurological Diseases and Stroke (NINDS). These two institutes now lead a trans-NIH neurosciences initiative. One of its components is the Human Brain initiative, which supports research on and development of advanced technologies and infrastructure through cooperative efforts among neuroscientists and information scientists. The goal is to produce new digital capabilities in an Internet-based information management system.

In addition to its support of biologically-oriented medical research, the NIH has had a long and growing commitment to behavioral and social scientific research relevant to health. Almost all NIH institutes and centers have played a role, but NIMH has remained the largest single source of support for behavioral research and social science. Following President Lyndon B. Johnson's call in the 1960s to apply research to the alleviation of social and public health problems, NIMH established various topic-focused centers on basic and applied research, training, demonstration grants, and technical assistance related to issues such as crime and delinquency, suicide, inner-city problems, mental health and aging, minority group mental health, and substance abuse and alcoholism. In 1968, NIMH was moved out of NIH to become a part of the newly created Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA). Research components of NIMH, the National Institute on Alcoholism and Alcohol Abuse (NIAAA), and the National Institute on Drug Abuse (NIDA) rejoined the NIH in 1992.

In addition, in the 1970s the National Heart, Lung, and Blood Institute (NHLBI) developed a pioneering extramural program on health and behavior, and the National Institute on Child Health and Human Development (NICHD) as well as the National Institute on Aging (NIA) established broad-ranging programs in support of basic and applied behavioral and social research. In 1979, ADAMHA and NIH jointly commissioned a landmark study by the Institute of Medicine entitled *Health and Behavior: Frontiers of Research in the Biobehavioral Sciences* (Washington, DC: National Academy Press, 1982) that gave direction to NIH's expanding activities in the behavioral and social sciences. Organizationally, NIH recognized the need to coordinate its activities across the institutes and centers, and in 1982 it established the NIH Working Group on Health and Behavior (now called the NIH Behavioral and Social Sciences Research Coordinating Committee). In 1993, Congress established the Office of Behavioral and Social Sciences Research (OBSSR) in the Office of the Director, NIH, in recognition of the key role that behavioral and social factors often play in illness and health. The OBSSR mission is to stimulate behavioral and social sciences research throughout NIH

and to integrate these areas of research more fully into other areas of NIH health research, thereby improving the understanding, treatment, and prevention of disease. Currently, about 10 percent of the NIH budget is devoted to behavioral and social sciences research and training across its various programs.

In 1999, Congress made a commitment to double the NIH budget by 2003. The additional monies have been invested in several highly promising lines of research. One achievement from the investment in genomics—the map of the human genome—is perhaps the best known. Other areas include protenomics, the analysis of large sets of proteins with the goal of understanding their function; combinatorial chemistry, which provides a new way to generate large libraries of molecules that can be screened for use as drugs; and new, advanced imaging techniques.

NATURAL SELECTION

Definitions of natural selection vary due to the long history of the discussion of this topic. According to Darwin's theory of evolution, natural selection signifies the phenomenon that in the struggle for life only the favorable variants of a potentially much larger progeny survive. Advantageous variations accumulate, and thus descendants finally diverge from the ancestors until—in the long run—new species evolve.

Apart from a few exceptions, most contemporary biologists and other scholars regard natural selection as a real process in nature. However, the evaluation of the extent to which natural selection contributes to the origin of species varies significantly among them. For the neo-Darwinian school of biologists, natural selection is the key process for the origin of all life forms on earth. However, for most other biologists it is of only limited significance and thus largely incapable of explaining the origin of species, and especially higher systematic categories. Between these views all possible intermediates can be found.

Basic problems for the theory of natural selection include: (1) the virtual inaccessibility of past events, and (2) the fact that even at present, putative selection processes are hardly attainable for rigorous scientific investigation.

With regard to the modern synthesis, with its ideas of selection of mutations with "slight or even invisible effects on the phenotype" (Mayr) within a high number of offspring, by the 1950s, French biologists such as Cuenot, Tetry, and Chauvin raised the following objection (according to Litynski, 1961):

> Out of 120,000 fertilized eggs of the green frog only two individuals survive. Are we to conclude that these two frogs out of 120,000 were selected by nature because they were the fittest ones; or rather—as Cuenot said—that natural selection is nothing but blind mortality which selects nothing at all?

If—as in many other cases—only a few out of millions and even billions of individuals are to survive and repro-

duce, then there is some difficulty in believing that those few should really be the fittest. Strongly different abilities and varying environmental conditions can already turn up during different phases of ontogenesis. Distances between and hiding places of predator and prey, local differences of biotopes and geographical circumstances, and weather conditions and microclimates all belong to the repertoire of infinitely varying parameters. One may therefore agree with King Solomon, who stated in 1000 B.C.: "I returned, and saw under the sun, that the race is not to the swift, nor the battle to the strong . . . but time and chance happeneth to all of them."

Population genetics has attempted to quantitatively assess this problem. Fisher (1930) calculated that new alleles with even 1% selective advantage will routinely be lost in natural populations with more than 90% probability in the next 31 generations. Chance occurrences like genetic drift (random fluctuations of gene frequencies in populations) seem to play a rather underestimated role in nature. Moreover, variation due to modifications can strongly surpass the effects of the mutations mentioned previously.

In spite of the objections listed earlier concerning the limits of natural selection as a general principle in nature, some survival-of-the-fittest apparently takes place. Although largely caused by human activities, the emergence of new alleles and plasmids with strong selective advantage, as in the cases of multiple resistance in bacteria and resistances due to DDT in insect species, have often been cited as evidence of natural selection in action.

The discussion between biologists and other scientists, therefore, deals with the question of the extent to which natural selection takes place in nature, and whether it is actually an omnipotent principle that explains the diversity of all life forms.

To be sufficient, the selective principle considered above depends on adequate numbers of creative mutations to occur, constituting the basis upon which selection will work. However, in large mutagenesis experiments the number of new phenotypes due to mutations regularly proved to be limited and followed a saturation curve (see the *law of recurrent variation,* Lönnig, 2002).

Also, on the morphological/structural level severe difficulties exist for natural selection. A major problem is the origin of irreducibly complex structures. "An irreducible complex system is one that requires several closely matched parts in order to function and where removal of one of the components effectively causes the system to cease functioning" (Behe, 1998, p.179). The often quoted example of the bacterium flagellum with filament, hook, and motor embedded in the membranes and cell wall has not, in fact, been explained by natural selection (for further examples, see Behe, 1996). But even for many simple structural differences, such as the wide variety of different kinds of leaf margins in plants, few selective advantages have been detected so far. Thus, qualitative as well as quantitative limits in generating selectively advantageous mutations point to the limits of the theory of natural selection.

The objection raised by the philosopher Sir Karl Popper that "Darwinism is not a testable scientific theory but a *metaphysical research program,*" that is, natural selection was seen to be "almost tautologous" (1974), has so strongly been contested by neo-Darwinians and others that four years later he retracted some of his arguments and stated that "the theory of natural selection may be so formulated that it is far from tautological" (1978). As evidence, he mentioned the famous textbook example of natural selection termed the "industrial melanism" of the peppered moth (*Biston betularia*).

However, 20 years after Popper's partial retraction, Coyne (1998) and other biologists have stated that the whole case is flawed. They note that: (1) peppered moths normally do not rest on tree trunks, (2) they choose their resting places during the night, and (3) the return of the variegated form occurred independently of the lichens "that supposedly played such an important role" in the evaluation of the phenomenon (for an extensive recent discussion, see Hooper, 2002). Thus, Popper's partial retraction is not substantiated by the only case he mentioned, and his original criticism of metaphysics seems still to be more valid than he later imagined.

In the search for possible alternatives to explain the complexity and divergence of life forms, one of the hypotheses—the concept of Intelligent Design—integrates the difficulties arising from statistical improbabilities as well as the morphological and functional problems that have not been solved by the modern synthesis.

NATURALISTIC OBSERVATION

Naturalistic observation refers to the unobtrusive and nonreactive study of organisms in their native habitat or environment, devoid of researcher manipulation, intrusion, or controls. The naturalness of the study environment, however, is to be interpreted as a continuum rather than as a dichotomy (Dane, 1994). Fossey's (1983) study of the mountain gorillas in their natural habitat in Zaire (1983); Goodall's (1986) study of chimpanzees in the forests of Gombe; and Schaller's study of gorillas in Zaire, pandas in China, and wildlife in the Tibetan steppe (Schaller, 1963, 1993, 1998) are examples of recent naturalistic observation studies conducted by ethologists. In addition to animal ethology, naturalistic observation techniques have been widely used in psychology, anthropology, sociology, and education to study human beings as well. Among the large number of topics that are studied using naturalistic observation techniques are instinctive behavior, imprinting, evolution, play, stimuli, communication and signals, feeding, hunting, learning, memory, adaptation, organizations, courtship and mating, cooperation, competition, migration, environment, depression, mental illness, children at play, and ecology. The studies encompass animals, birds, fish, and human beings.

Though systematic usage of naturalistic observation is of recent origin, it is one of the oldest methodologies in science. The development of naturalistic observation may be roughly divided into three periods: (1) antiquity to 1920, (2) 1920 to 1950, and (3) post 1950s. Its origins can be traced back to prehistoric times, rooted in oral traditions and observable in cave paintings. Many explorers, travelers, and journalists have contributed observational accounts of their own or other societies. During the last century, naturalists including Charles Darwin carried out more systematic fieldwork.

The second period, between 1920 and 1950, has been described as the classical period of ethology (Crist, 1999). This period witnessed basic and comprehensive changes in naturalistic observation research that continue to evolve today. Theoretical perspectives were introduced during the latter part of this period in order to understand and explain animal behavior.

After the 1950s, ecological perspectives and the study of human ethology were introduced (Willems & Raush, 1969). Similarly, sociobiological perspectives, evolutionary psychological approaches, and the area of cognitive ethology were also introduced during this period. Behavior therapists began to use direct observation in collecting specific behavioral data in natural settings (Hutt & Hutt 1970; Johnson & Bolstad, 1973; Mash & Terdal, 1976), and clinicians extended their observations from individuals to organizations. The works of Lorenz, Tinbergen, and von Frisch were awarded the Nobel prize in 1973, and the prize provided a prestigious acknowledgment of the contributions of ethology (Tinbergen, 1985). More recently, ideas from other disciplines such as game theory, optimality theory from economics, and handicap principles from sports have been borrowed to study animal behavior in the context of competing demands for food and safety.

Technology has significantly impacted the naturalistic observation methodology in recent years. The availability of versatile audio equipment, sophisticated digital video equipment, and powerful computers has extended the scope, range, and attractiveness of naturalistic observation and has made possible the dissemination of observations and findings to much larger audiences.

Conducting Naturalistic Observation Studies and Research Issues

Though the naturalistic paradigm has been shared by different disciplines, the research techniques in those fields vary significantly (Arrington, 1943; Brandt, 1972; Denzin & Lincoln, 1994; Dewsbury, 1985; Hammersley, 1992; Liebow, 1967; Lincoln & Guba, 1985; Malinowski, 1953; Pelto & Pelto, 1978; Taylor & Bogdan, 1984; Weick, 1985.) Researchers who study animals have commonly addressed five types of questions. These questions refer to the function, evolution and adaptation, causation, development of behavior, and stages of development. Some of these studies are comparative in nature. Laboratory studies of animals are used to study the physiology and neural control of behavior that is not affected by captivity or the artificiality of the laboratory. Another set of studies covers anthropological, sociological, and educational perspectives focused on understanding and explaining groups, societies, and cultures in different contexts. The complexity of human beings and their social structure has necessitated the use of supplemental tools and techniques such as laboratory studies, interviews, projective techniques, multisite studies, informants, multidimensional rating scales, and content analysis.

At various times, issues have been raised about naturalistic observation's importance, methodological validity and reliability, generalizability, replicability, intrusion by researchers, and interpretation of behavior, especially human behavior. The work of Darwin, for example, has been analyzed and scrutinized for its anthropomorphism (Crist, 1999, pp. 11–51). Questions about sampling raised by Arrington (1943) more than 50 years ago are relevant even today. Nevertheless, naturalistic observers have addressed many of these problems, and it is now generally recognized that social and behavioral sciences cannot always be devoid of researcher selectivity and bias (Asquith, 1991; Haraway, 1989).

Trends

It is clear that naturalistic observation methods have gained legitimacy among academic disciplines. The search for nat-

uralistic conditions or environments even in the context of experimental designs (Gibbons, Wyers, Waters, & Menzel, 1994) is an illustration. Studies of the animal kingdom, fish, and birds have also gained wide popularity among the general public through the media, especially television. Researchers such as Goodall and Fossey are now known outside their own fields. Recent discoveries of the closeness between the animal kingdom and human beings have provided an economic rationale for such studies as well. With the introduction of new topics such as ecology, the debate surrounding controversial topics such as cognitive ethology, and the advent of significant technological breakthroughs, the techniques of naturalistic observation are likely to be even more widely used and accepted in the future.

NATURE–NURTURE CONTROVERSY

The so-called nature–nurture controversy is a family of controversies about the relative roles of heredity (nature) and environment (nurture) in shaping human characteristics. These controversies exist not so much because the scientific questions involved are difficult—although many are—but because the proposed alternative solutions are perceived as having profound implications for cherished beliefs concerning human equality, social justice, and individual responsibility.

Although precursors of the nature–nurture controversy may be found in the writings of the ancient Greeks, its modern form can be traced back fairly directly to the philosopher John Locke (1632–1704) on the one hand, and the naturalist Charles Darwin (1809–1882) on the other.

Locke may be considered the chief ideological father of the nurture side of the controversy. In *An Essay Concerning Human Understanding* (1690), he invoked the metaphor of the mind as a blank sheet of paper on which knowledge is written by the hand of experience. His political view that all men are by nature equal and independent had

a strong influence on the theorists of the American and French revolutions. In Locke's own view, human political equality was not inconsistent with an inborn diversity of human tendencies and capabilities. In *Some Thoughts Concerning Education* (1683, §101) he wrote, "Some men by the unalterable frame of their constitutions are stout, others timorous, some confident, others modest, tractable, or obstinate, curious, or careless, quick or slow. There are not more differences in men's faces, and the outward lineaments of their bodies, than there are in the makes and tempers of their minds." Nevertheless, Locke judged the bulk of human variation to be the result of differences in experience (§1): "I think I may say, that of all the men we meet with, nine parts of ten are what they are, good or evil, useful or not, by their education."

Darwin gave the nature side of the controversy its modern form by placing the human mind solidly in the framework of biological evolution. In *The Descent of Man* (1871) and *The Expression of the Emotions in Man and Animals* (1872), Darwin made it clear that human behavior shared common ancestry with the behavior of other animal forms, and that behavioral as well as physical characters were subject to the basic evolutionary mechanism of genetic variation followed by natural selection of the variants most successful in their environments. Darwin's younger cousin, Sir Francis Galton, enthusiastically applied Darwin's ideas to the interpretation of human differences. Galton invented mental testing, and also founded the eugenics movement, which aimed to improve humanity by encouraging the more able to have larger families and the less able to have smaller ones.

Another aspect of the Darwinian continuity of humans with other animals was emphasized by the psychologist William McDougall in the early part of the twentieth century. McDougall developed a social psychology around the doctrine of instincts, the idea that "the human mind has certain innate or inherited tendencies which are the essential springs or motive powers of all thought and action" (McDougall, 1908, p. 20). Examples of such inherited tendencies cited by McDougall were the instincts of gregariousness, self-assertion, curiosity, flight, repulsion, pugnacity, acquisition, construction, parental care, and reproduction.

Both McDougall's instinct doctrine and the Galtonian notion of inherited individual differences in capacities were vigorously rejected in the radical behaviorism of the psychologist John B. Watson, who in 1925 issued a famous challenge: "Give me a dozen healthy infants, well-formed, and my own specified world to bring them up in and I'll guarantee to take any one at random and train him to become any type of specialist I might select . . . regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors" (Watson, 1925, p. 82).

The next few decades of the nature–nurture debate were marked by an increasing emphasis on empirical research, involving identical and fraternal twins, adoptive families, and other informative groups. In a series of 1959 lectures (published in 1962 as *Mankind Evolving*), the geneticist Theodosius Dobzhansky elegantly integrated Darwinian concepts with an appreciation of the role of culture in human evolution and Lockean democratic ideals. By 1960, with the publication of the textbook *Behavior Genetics* by J. L. Fuller, a biologist, and W. R. Thompson, a psychologist, it appeared that the nature–nurture controversy might at last be becoming ordinary science.

The calm was illusory. In 1969 the educational psychologist Arthur R. Jensen published a long article in the *Harvard Educational Review* entitled, "How much can we boost IQ and scholastic achievement?" Jensen took a fairly strong hereditarian position, estimating that about 80% of individual variation in IQ was genetic. To make matters worse, he conjectured that at least part of the persistent disadvantage of U.S. Blacks in IQ test performance was also genetic in origin.

In 1974, the psychologist Leon Kamin in *The Science and Politics of I.Q.* launched an assault on human behavior genetics and its political uses. A more moderate critique was that of the sociologist Christopher Jencks and his colleagues in their book, *Inequality* (1972). Then in 1975, a new front opened up with the publication by the zoologist Edward O. Wilson of *Sociobiology,* which outlined a modern population-genetic basis for the notion that biological instincts might play a central role in human affairs. Not all of the action inspired by these controversies was genteel academic debate—tires were slashed and speakers assaulted. In 1994, a new round of controversy was touched off by R. J. Herrnstein and C. Murray's book *The Bell Curve,* which examined the role of intelligence in American life.

Early in the twenty-first century, with cloning and the sequencing of the human genome in the news, it appears that nature–nurture controversies have not yet run their course. It would not do to conclude, however, that no progress has been made since the days of Locke and Darwin. Modern views of biological evolution, while deriving from Darwin, are more complex, differentiated, and mathematical than his. Modern psychology takes—in its better moments—a vastly more sophisticated view of the organism-environment interplay than the instinct lists of McDougall or the behavioristic battle cries of John B. Watson. Finally, nature–nurture controversialists must accommodate their prejudices to a much larger body of evidence today than in the past. Even though nature–nurture controversies continue, they themselves also evolve.

NEAR-DEATH EXPERIENCES

Near-death experiences are profound psychological events occurring in individuals close to death or facing intense physical or emotional danger. Although the term *near-death experience* and its acronym NDE were not coined until 1975, accounts of similar events can be found in the folklore and writings of most cultures. The phenomenon was first described as a clinical syndrome in 1892, although isolated cases appeared in medical journals throughout the nineteenth century. Once thought to be rare, NDEs have been documented to occur in 10% to 20% of cardiac arrest survivors.

Moody, who coined the term *near-death experience,* used it to refer to an ineffable experience on the threshold of death that may include hearing oneself pronounced dead, feelings of peace, unusual noises, a sense of movement through a dark tunnel, a sense of being out of the physical body, meeting other spiritual beings, meeting a being of light, a life review, a border or point of no return, and a return to the physical body, followed by profound changes in attitudes and values and elimination of one's fear of death. Noyes and Slymen factor-analyzed the features reported by near-death experiencers into (1) mystical elements, such as a feeling of great understanding, vivid images, and revival of memories; (2) depersonalization elements, such as loss of emotion, separation from the body, and feeling strange or unreal; and (3) hyperalertness elements, such as vivid and rapid thoughts and sharper vision and hearing. Ring proposed a model of NDEs unfolding in sequential stages of peace and contentment, detachment from the physical body, entering a darkness, seeing a brilliant light, and entering a supernal realm of existence.

Some investigators have identified different types of NDE. Sabom categorized NDEs as autoscopic, involving an apparent out-of-body experience; transcendental, involving an apparent passage of consciousness into another dimension; or combined, involving features of both types. Greyson classified NDEs as cognitive, dominated by altered thought processes; affective, dominated by changes in emotional state; paranormal, involving purported psychic elements; or transcendental, characterized by apparently mystical or otherworldly features.

Recent studies suggest that how one comes close to death may influence the type of NDE. NDEs dominated by cognitive features, such as temporal distortions, accelerated thoughts, and a life review, are more common in near-death events that are sudden and unexpected than in those that may have been anticipated. NDEs associated with cardiac arrest resemble out-of-body experiences, while those without cardiac arrest are more similar to depersonalization, in which one feels oneself or one's body to be unreal. NDEs occurring to intoxicated persons tend to be bizarre and confused, like hallucinations. Although all elements of the NDE can be reported by individuals who merely perceive themselves to be near death, an encounter with a brilliant light, enhanced cognitive function, and positive emotions are more common among individuals whose closeness to death can be corroborated by medical records.

Retrospective studies of near-death experiencers show them to be psychologically healthy individuals who do not differ from comparison groups in age, gender, race, religion, religiosity, mental illness, intelligence, neuroticism, extroversion, trait and state anxiety, and relevant Rorschach measures. Some studies suggest that the experiencers are good hypnotic subjects, remember their dreams more often, are adept at mental imagery, and tend to acknowledge more childhood trauma and resultant dissociative tendencies than nonexperiencers. It is not known whether these personal traits and recall of prior experiences are the results of an NDE or premorbid characteristics that predispose people to have NDEs when they come close to death.

Several physiological and psychological models have been proposed to explain NDEs, although there has been almost no research testing etiological hypotheses. A plausible psychological explanation suggests that NDEs are products of the imagination, constructed from personal and cultural expectations to protect us from facing the threat of death. However, individuals often report experiences that conflict with their specific religious and personal expectations of death. Although there are some cross-cultural variations in the content of NDEs, these may reflect simply the experiencers' difficulty processing and expressing an experience that is largely ineffable. Specific knowledge individuals had

about NDEs previously does not influence the details of their own experiences; people who have never heard or read of NDEs describe the same kinds of experiences as do people who are quite familiar with the phenomenon. Furthermore, children too young to have received substantial cultural and religious conditioning about death report the same kinds of NDEs as do adults; some cases have been reported to have occurred before the child could have acquired any language skills.

Several neurobiological models have been proposed for the near-death experience, invoking the role of endorphins or various neurotransmitters, and linking the NDE to specific sites in the brain. At this point, such models are speculative and none has been tested. A plausible assumption is that NDEs are hallucinations produced either by drugs given to dying patients or by metabolic disturbances or brain malfunctions as a person approaches death. However, many NDEs are recounted by individuals who had no metabolic or organic conditions known to cause hallucinations. Organic brain malfunctions generally produce clouded thinking, irritability, fear, belligerence, and idiosyncratic visions, quite incompatible with the exceptionally clear thinking, peacefulness, calmness, and predictable content that typifies near-death experiences. Visions in patients with delirium are generally of living persons, whereas those in NDEs are almost invariably of deceased persons. Furthermore, patients who are febrile, anoxic, or given drugs when near death report fewer and less elaborate NDEs than do patients who remain drug-free. That finding may suggest that drug- or metabolically-induced delirium, rather than causing NDEs, in fact inhibits them from occurring, or alternatively that delirious patients tend not to recall their experiences upon recovery.

Regardless of their cause, NDEs may permanently and dramatically alter the individual experiencer's attitudes, beliefs, and values. Aftereffects most often reported, corroborated in long-term follow-up studies including interviews with near-death experiencers' significant others, include increased spirituality, compassion and concern for others, appreciation of life, belief in postmortem existence, sense of purpose, and confidence and flexibility in coping with life's vicissitudes, as well as decreased fear of death, interest in materialism, and competitiveness. Although decreased fear of death has been associated with increased suicidal risk, near-death experiencers paradoxically express stronger objections to suicide than do comparison samples, primarily on the basis of increased transcendental beliefs.

NEOCORTEX

The two cerebral hemispheres comprise the most anterior and visible portion of the mammalian brain. In humans, most of the surface of these hemispheres is covered by highly convoluted neocortex (*cortex,* derived from Greek, means bark or covering). Neocortex is found only in mammals, and is differentiated from more primitive types of cortex by a complex morphology and lamination pattern. This tissue may be considered the "crown jewel" of mammalian evolution, having expanded more than any other brain region during our evolutionary history. The characteristic convolutions of the cortical surface represent a clever geometric solution to the challenge of fitting more of the two-dimensional neocortical sheet into a braincase without unduly increasing the size of the head. In humans, the neocortex occupies about 80% of the brain mass and is essential for rational thought, language, perception, and goal-directed behavior.

The neocortex is approximately 2 mm thick and consists of some 12 billion neurons. About 70% of these are large "pyramidal" shaped cells and the remainder are smaller "stellate" shaped cells. Functionally, cortical neurons may be classified based on whether they excite or inhibit their synaptic targets. Whereas pyramidal neurons are excitatory, different types of stellate neurons may be either excitatory or inhibitory. An imbalance of excitation and inhibition can lead to pathological states such as epileptic seizure activity.

Most of the neocortex is made up of six distinct layers of cell bodies and processes. These layers differ from one another in the size and density of their cell bodies and in the relative proportion of neurons of different types. The functional operations of the neocortex may divided into three general components: (1) reception of neural information from subcortical and cortical brain regions (via synaptic inputs), (2) integration of this information, and (3) organization of output signals that are projected to the many targets of the neocortex.

The cortical layering pattern is related to these basic functions. For example, layer IV of sensory neocortex receives information from lower sensory structures. This information is integrated, and synaptic excitation flows up-

ward and downward to superficial and deeper layers of the cortex. Finally, pyramidal neurons within these various layers further integrate this information and project the results of this processing (in the form of trains of action potentials) to both subcortical and cortical targets. This vertical spread of activation reflects the organization of the cortex into functional columns or modules, which have been found in many cortical regions. Thus, the cortical column represents a basic functional processing unit, consisting of thousands of neurons spanning the six cortical layers. The entire neocortex is thought to contain hundreds of thousands of such functional columns. The power of the mammalian neocortex as an engine of information processing is thought to result, in part, from the simultaneous, parallel operation of thousands of such cortical columns.

Functionally, neocortex can be divided into sensory, motor, and association areas. Each sensory modality has multiple cortical representations that are organized in a hierarchical manner. For example, the primary visual cortex (in the occipital lobe) performs the initial cortical processing of visual information. Higher visual cortical areas are specialized in analyzing color, motion, and other functional aspects of vision. These areas communicate their analyses to the inferotemporal cortex, which is necessary for object recognition. Thus, whereas primary visual cortex is essential for visual sensation, inferotemporal cortex is essential for perception of objects. Other sensory modalities as well as motor-related areas are organized in a similar hierarchical manner. Most of the neocortex (approximately 75%) cannot be divided into sensory or motor areas and is referred to as "association" cortex. There are many such areas, some of which support the highest cognitive abilities such as language, foresight, and abstract reasoning.

Each of the two cerebral hemispheres can be divided into frontal, parietal, occipital, and temporal lobes. These cortical regions are related to certain sensory, motor, or cognitive functions. A brief overview of the main functions and clinical syndromes associated with the cortical lobes is as follows:

The *occipital lobes* are the hindmost cortical lobe and contain regions necessary for vision. The posterior pole of the occipital lobe is known as the primary visual cortex, and lesions here can produce blindness in the contralateral visual field. More specific visual disorders result when brain damage also includes neighboring temporal or/and parietal lobes. For example, lesions to occipitotemporal regions can produce visual agnosias, such as a deficit in recognizing objects, colors, or faces, despite otherwise normal vision.

The *parietal lobes* constitute the dorsal and lateral area of each hemisphere and mediate somatosensory information from the body including touch, pain, temperature, and limb position. The parietal lobes also play an important role in higher visual processing and in attending and integrating sensory information from different modalities. Parietal lobe lesions can often cause a striking deficit called unilateral neglect, in which a patient ignores visual, auditory, and somatosensory information coming from the side of the body contralateral to the brain lesion.

The *temporal lobes* contain cortical areas involved in auditory and higher visual processing and areas crucial for learning, memory, multimodal integration, and emotion. Lesions to the temporal lobes' primary auditory area can cause partial or complete deafness. Lesions to associated areas can cause more selective hearing deficits. For example, temporal lobe lesions in the left hemisphere are often associated with disorders of speech perception, while lesions to the symmetrical areas in the right hemisphere can produce deficits in music perception. Within the temporal lobes are structures that are part of the limbic system, which is phylogenetically older than the neocortex. These structures are crucial for forming long-term memories and for emotional behavior.

The *frontal lobes* occupy almost one half of each cerebral hemisphere in humans. The frontal lobes play a major role in motor activity (control of body movements), participate in language functions, and are important for higher integrative functions, personality traits, emotionality and "executive" control (the translation of thought into action). Damage to the primary motor area can cause paralysis on the contralateral side of the body. Fluent speech production is associated with a region (Broca's area) in the left frontal lobe. A large portion of frontal lobes called the prefrontal cortex is involved in a variety of complex cognitive functions such as problem solving, planning action toward a goal, and using information flexibly.

The two cerebral hemispheres are largely symmetrical in both structure and function. Some important functions, however, are organized primarily within a single hemisphere. The left hemisphere of almost all right-handed and most left-handed people is essential for many language-related functions. Injuries to specific areas of the left hemisphere often result in language related disabilities such as Broca's aphasia (difficulty with speech production), Wernicke's aphasia (difficulty with comprehension), agraphia (inability to write), or alexia (inability to read). In contrast, the right hemisphere is superior for emotional speech intonation (prosody), appreciation of humor, and visuospatial integration such as recognition of objects and faces. A massive fiber bundle, the corpus callosum, is responsible for communication between the two hemispheres and for coordinating their activity. When this pathway is destroyed the two hemispheres may begin to act independently. The careful study of such "split-brain" patients has led to many remarkable insights into neocortical organization.

NEURAL NETWORK MODELS

Models containing networks of neuronlike units are the central feature of "connectionist," "parallel distributed processing," and "spreading activation" theories. Mathematically, neural networks form a system of computation that is cooperative and self-organizing. Behavior that seems to follow a plan, schema, or strategy emerges from the interactions among the units, without the presence of a supervisory system.

Network Units

Each unit in a neural network is described by two rules. First, the *activation rule* combines inputs and generates an output called an activation level. Second, the *learning rule* alters the transmission of activation levels between one unit and the next.

Activation rules explain how neurons perform logical and mathematical operations (McClulloch & Pitts, 1943). Each unit receives activation levels from either sensory receptors or other units. These inputs usually have a value of either 0 or 1. An input value of 1 will activate its connection with the unit. The connection itself has a value between –1 and +1, which is called the *connection weight.* It expresses the efficiency of transmission of the input level across a synapse between units. The total input level to a unit at any one moment is the sum of the active input weights. If the total input level exceeds a threshold value, then the unit will be triggered, and the activation level of its output will rise from 0 to 1.

By manipulating connection weights and threshold values, it is possible to produce common logic functions. For example, an AND function can be constructed if a unit with a threshold of .75 has two inputs, each with a connection weight of .50. If only one input is active, the total input level will be too low to trigger an output. If, however, both inputs are active, the total input level would be 1.0, exceeding the threshold and thereby triggering the output. The same unit can be converted to an OR function either by lowering the threshold value to less than .50 or by raising each input weight to a value greater than .75.

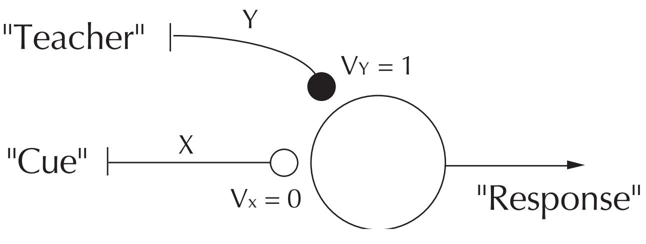

Figure 1. Hebbian adaptive unit, in which X denotes the "cue" input level, V_X denotes an adaptive connection weight, Y denotes the "teacher" input level, V_Y denotes the fixed connection weight, and "response" denotes the output level.

Learning rules for networks are based on the Law of Contiguity (Hebb, 1949, p. 50; James, 1892/1984, p. 226). These rules contend that synaptic transmission increases in efficiency whenever presynaptic activity has been contiguous with postsynaptic activity. Figure 1 shows an example of a unit capable of learning. One input (X), here called the "cue," has no initial connection weight ($V_X = 0$) and thus is unable to trigger the unit. The other input (Y), here called the "teacher," has a fixed, large weight ($V_Y = 1$) that can trigger the unit's "response" output. The cue input provides presynaptic activity, and the teacher input induces postsynaptic activity. In mathematical terms, the change in connection weight (ΔV_X) is a product of the two levels of activity, written as $\Delta V_X = (cXY)$ where c is the learning rate ($0 < c < 1$) (Sutton & Barto, 1981). This formula is usually called the "Hebbian rule."

While the operation of the Hebbian rule depends on the contiguity of activation levels, another widely used rule assumes that learning depends on the difference between the cue's input weight and the teacher's input weight, $\Delta V_X = c(V_Y - V_X)$ (Sutton & Barto, 1981). This rule is known variously as the error-correction rule, the delta rule (Rumelhart, Hinton, & Williams, 1986), the Rescorla-Wagner rule (Rescorla & Wagner, 1972), and the least-mean squares rule (Gluck & Bower, 1988).

Basic Architectures

Layered Networks

Figure 2 shows a layered network. It has a layer of sensory inputs, each of which projects to an intermediate layer of "hidden" units, which send their outputs to a third layer of response units. Layered networks have proved crucial in resolving difficult issues of stimulus representation and

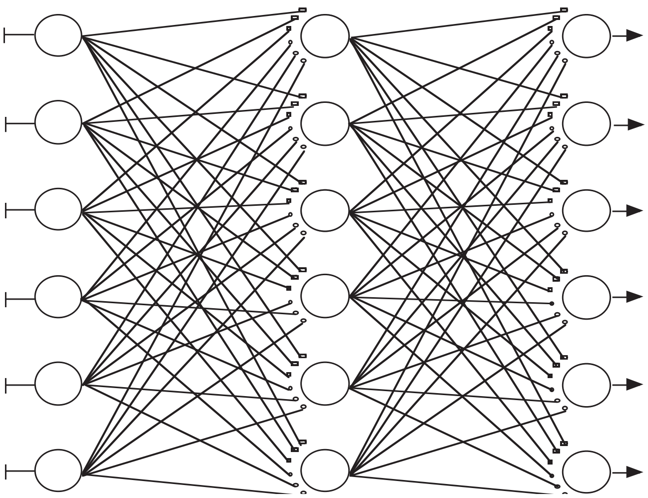

Figure 2. A layered network with three layers. The left-hand layer receives inputs from the environment and projects to the second layer of "hidden" units, which projects to a layer of output units.

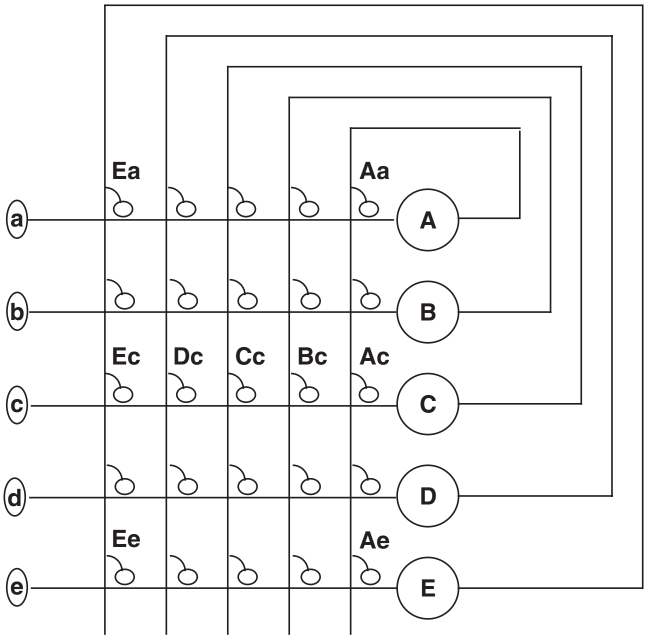

Figure 3. An autoassociative network, in which all output levels can be associated with input levels.

concept formation. Specifically, layered networks provide a basis for learning arbitrary mappings from stimulus input patterns to response output patterns. For example, each distinctive combination of sensory inputs can acquire connections to one of the hidden units. In turn, that hidden unit can acquire a connection with one of the response outputs in the final layer.

Autoassociative Networks

Autoassociative networks feed their outputs back as inputs. Figure 3 shows a small autoassociative network. Each of five units (A, B, C, D, E) receives one external input (a, b, c, d, e). These external inputs have fixed connections that can trigger an output from their respective units. Each unit also receives five recurrent inputs, one from each unit's output including its own. For example, as shown in Figure 3, the C unit has five recurrent connections, designated as Ac, Bc, Cc, Dc, and Ec. These connections are modifiable; whenever an output and an input are both active, a positive connection weight can grow at their intersection, according to a Hebbian rule.

Autoassociative networks can perform three functions that are of interest in psychology:

1. *Pattern completion.* After training, only a portion of the original inputs can retrieve the entire pattern of outputs. If inputs a and e are repeatedly presented together, four interconnections would be established, namely Aa, Ae, Ea, and Ee. Subsequently, the a input alone would trigger both the A and E outputs via the Aa and Ae connections. Likewise, the e input would trigger both outputs via the Ea and Ee connections.

2. *Noise tolerance.* Provided that successive sets of inputs are not entirely random, the pattern of the interconnections will reflect any underlying prototypic set, even if the prototype itself is never presented. Thus, a new set of inputs that is similar to the prototypic set can retrieve the prototypic pattern. This feature of autoassociative networks allows them to be used to explain stimulus generalization, pattern recognition, and categorization.

3. *Superimposed storage.* Autoassociative networks can store a large number of input sets. This feature allows for the retrieval of both prototypic patterns and specific, frequent exemplars (Kohonen, 1984, pp. 160–167; McClelland & Rumelhart, 1985).

NEUROCHEMISTRY

Early neurochemists established that the brain is enriched with fatty substances (lipids), many of which are unique to the nervous system. Long, highly unsaturated fatty acids occur as components of brain phospholipids and glycolipids.

The brain also contains cholesterol, but unlike other body organs, has little or no cholesterol ester or triglyceride. The human brain contains about 10% lipids, 10% protein, and 78% water. The remaining 2% consists of DNA, RNA, electrolytes, and other materials. White matter is enriched in nerve axons ensheathed in multilayered, lipid-rich membranes (myelin) produced by oligodendroglia, while gray matter contains mainly neuronal cells and support cells (the astroglia), interposed between the neurons and cerebral blood vessels.

The human brain weighs about 1400 grams, or 2% of body weight. Its pale appearance belies the fact that about 15% of the cardiac output is required to supply it with glucose and oxygen, and to remove metabolic wastes. The brain is efficient in this exchange and thus accounts for about 20% of the resting basal metabolic rate. Chemical energy for the working of the brain is generated in the form of 38 molecules of ATP (adenosine triphosphate) per molecule of glucose metabolized. By means of an intravenously injected glucose analogue (^{14}C-2-deoxyglucose), it was demonstrated that brain metabolism in experimental animals could be regionally activated (e.g., in the occipital cortex during visual stimulation). Stimulated regional cerebral blood flow (rCBF) also occurs. These metabolic correlates of brain activity can be measured noninvasively in human subjects by means of radiolabeled tracers and positron emission tomography (PET). Regional brain activation can also be studied by functional magnetic resonance imaging (fMRI).

While hydrophilic and ionically charged small molecules readily diffuse from blood into most body organs, they are excluded from the brain and spinal cord by the blood-brain-barrier (BBB). Exceptions are glucose, vitamins, essential amino and fatty acids, and other essential nutrients, for each of which special transport systems exist. While the BBB protects the brain, it necessitates molecular legerdemain in designing effective drugs.

The high energy needs of the brain reflect the enormous volume of information it can integrate at great speed: sensory inputs, central processing, storage, and retrieval on the one hand; and neural and neuroendocrine outputs that control the body's vital functions and behavioral expression on the other. All of this is mediated by neurons, via coded electrical messages (conduction) and chemical messages (synaptic transmission).

Neuronal action potentials are conducted down the axon as rapid depolarization waves, typically terminating at the presynaptic region of another neuron. The electrical potential is generated by efflux of neuronal potassium and influx of sodium. Ultimately, the ionically based electrical gradients are restored by neuronal sodium extrusion and potassium influx. The recovery process requires the enzyme Na^+/K^+ATPase, which consumes ATP in the process. While the direction of information flow in neurons is generally unidirectional—from dendrite to cell body to axon—the supply of critical materials within the neuron is centrifugal: from cell body to the farthest reaches of both dendrites and axons. Proteins are formed primarily in the cell body, so cytoskeletal elements (microtubules, neurofilaments, actin, etc.) and organelles, including mitochondria and various vesicular structures, migrate centrifugally to the cell extremities via anterograde axonal transport, under the influence of "molecular motor" proteins, the kinesins. There is also centripetal, or retrograde, flow, mediated by dyneins and thought to transmit information from the synapse to the nucleus, for example to make more neurotransmitters or to initiate repair of damaged nerves.

Arrival of depolarization waves at presynaptic nerve endings initiates the process of neurotransmission with the release of chemical messenger molecules (neurotransmitters) such as acetylcholine, glutamate, gamma-aminobutyrate, glycine, norepinephrine, dopamine, and serotonin. These agents are released into the synaptic cleft in packets, following fusion of synaptic vesicles with the presynaptic membrane. The process of synaptic vesicle exocytosis and reformation by endocytosis involves many specialized proteins. A number of naturally occurring toxic agents, such as black widow spider venom and botulinum toxin, exert their action by disrupting this cycle.

Released neurotransmitters traverse the synaptic cleft and bind to specific membrane-spanning postsynaptic receptor proteins embedded in the plasma membrane, usually of another neuron. Note that the neurotransmitter molecule itself does not enter the postsynaptic cell, and is removed from the synaptic cleft quickly, to constitute an "off" signal. Occupied receptors respond in different ways, most commonly by the opening of ion channels or via an intervening guanine nucleotide binding protein (G-protein) that regulates the formation of an intracellular second messenger molecule, such as cyclic AMP, or of two phospholipid cleavage products, inositol trisphosphate and diacylglycerol. These chemical messages can in turn lead to intracellular calcium release, be amplified by various phosphoprotein/protein kinase cascades, or activate nuclear transcription factors, ultimately leading to a physiological outcome. The entire complex process of synaptic transmission can occur in milliseconds or take minutes. The actions of most neuroactive drugs, including stimulants, sedatives, anxiolytics, and antipsychotic agents, as well as illicit addictive substances, can be traced to their action on one or more steps in synaptic transmission.

Neurochemical studies on memory formation in a number of invertebrate and vertebrate species show that long-term, but not short-term, memory formation requires ongoing protein synthesis. It is generally held that long-term memory formation and other forms of neuroplasticity are mediated by altered synaptic relationships for which synthesis of new protein is required. Such conclusions, initially based on the behavioral effects of antibiotic blocking agents, have been further documented by genetic mutant, transgenic, and "knockout" studies, thus far primarily in fruit flies and mice.

Understanding of neuroscience at the molecular level has improved drug design. For example, administration of

DOPA, a precursor of dopamine that penetrates the BBB, alleviates the symptoms of Parkinson's disease resulting from a brain dopamine deficiency; inhibitors of acetylcholinesterase are effective in treating a brain acetylcholine deficiency in Alzheimer's disease; the blocking of presynaptic serotonin reuptake by fluoxetine (Prozac) relieves depression; a diet low in the amino acid phenylalanine prevents the mental retardation that otherwise occurs in an inborn defect in amino acid metabolism (phenylketonuria [PKU]). Numerous additional genetic defects that produce abnormal behavior have been identified in recent years, and in many instances, the biochemical phenotype, such as a defective protein, has been identified, an important first step in the eventual discovery of effective therapeutic strategies.

NEUROETHOLOGY

Neuroethology is the study of the neural basis of behavior, or how a certain coordinated pattern of movements (behavior) is planned and produced in response to a key stimulus by the integrated activity of different parts of the nervous system. This field emerged out of traditional ethology, or the study of animal behavior in a natural setting, when ethologists in collaboration with physiologists and anatomists began to investigate the relationship between brain structure/functions and observed behaviors. Main features of neuroethology include multidisciplinarity (with participation of disciplines such as ethology, neuroanatomy, neurophysiology, neuropharmacology, neuroendocrinology, and neuropsychology) and comparative approach (to identify basic principles of organization for the neural correlates of behavior). Aims and features of modern neuroethology have been reviewed in recent years (Spiro & White, 1998; Pfluger & Menzel, 1999).

The Neuroethological Approach

It is known from ethology that species-specific adaptive behaviors are elicited by key stimuli in the animal's environment that release a stereotyped behavioral response (fixed action pattern) when the internal or motivational state of the animal is appropriate. This program is known as an "innate releasing mechanism," although strong influences of learning have been recognized in behavioral responses. Tinbergen (1951) identifies at least seven different levels of neuroethological investigation: (1) the receptors and the sensory processes for identification of key stimuli; (2) the neuronal mechanisms for the localization of key stimuli; (3) the processes for the acquisition, retention, and recall of sensory information; (4) the neural correlates of motivational states; (5) how sensory information is processed to provide an organized motor output (the sensory-motor interface); (6) the neural circuits providing coordinated motor patterns; and (7) the ontogenesis and maturation of the neural elements involved in such processes.

In general, sensory systems are characterized by both anatomical and functional specializations for the detection and localization of the key stimuli (Capranica, 1983). In the brain, sensory systems are organized in the form of topographic maps representing the animal's sensory space. Similarly, motor systems are also topographically organized as maps representing the animal's body plan. Therefore, the sensory-motor interface includes brain mechanisms for communication between sensory and motor maps (Scheich, 1983). The coordinated activity of motor neurons resulting in the behavioral output (fixed action pattern) is likely to be determined genetically (Ewert, 1980). Finally, the whole process is modulated by neural structures influencing the animal's motivational state. For instance, hypothalamic nuclei are known to modulate aggressive (Anderson & Silver, 1998) or reproductive behaviors (Adler, 1983).

Classical studies in neuroethology include those on electrolocation (fish; Heiligenberg, 1991), echolocation (bats; Simmons, 1989), sound localization (owls; Knudsen, 1987), vocal learning (songbirds; Bottjer & Johnson, 1997), navigation and spatial learning (homing pigeons; Casini et al., 1997), and prey-catching behavior (toads; Ewert, 1997).

Genetic Approaches in Neuroethology

The genetic approach may help neuroethological research, especially in organisms such as *drosophila* that constitute classic experimental models for genetic manipulations (Heisenberg, 1997). Identified genetic variants may reveal new properties of neurons and can provide useful tools for interpretation of neuronal circuitries and their roles in complex behavioral systems.

Developmental Neuroethology

The term *developmental neuroethology* has gained a distinctive identity in defining the science that is specifically devoted to the investigation of the ontogeny of neural mechanisms underlying naturally occurring behaviors (Stehouwer, 1992). Issues in developmental neuroethology include, for instance: the roles played by hormones in the

ontogeny of neural circuits subserving species-specific behaviors; transient appearance of neural circuits of behavioral relevance that are not retained in mature animals; organization of behavioral sequences during ontogeny; and neural plasticity and learning in behavioral ontogeny.

Computational Neuroethology

Adaptive behavior is classically regarded as the result of the integrated activity of neural circuits. However, adaptive behavior does not depend solely on brain activity, but requires a continuous feedback between the nervous system, the body, and the environment. To understand these interactions, a methodology called *computational neuroethology* has been developed (Chiel and Beer, 1997). It is based on creating joint models of the relevant parts of an animal's nervous system, body, and environment to study the contributions of the components to adaptive behavior and the new phenomena that may emerge from their interactions.

NEUROIMAGING

Neuroimaging is the use of a variety of different techniques to map the location of different structural and functional regions within the living brain. It can be used clinically, as in identifying the location of a brain tumor, or in research, as in visualizing brain regions involved in complex behaviors or emotional states. The field of neurosciences is undergoing a radical acceleration in knowledge due to the use of these techniques and their potential for expanding our understanding of the brain correlates of thinking, feeling, and acting.

Structural neuroimaging techniques include methods that generate anatomic images of brain structures, while functional neuroimaging generates data that relate to the functioning of the brain, including measures of neuronal activity, cerebral metabolism, chemical composition, or neuroreceptor characteristics. Structural and functional techniques are often used in conjunction with one another as each technique provides different data. Selection of the specific imaging tool depends on whether the information will be used for clinical or research purposes, accessibility of the tool, the cost of the procedure, and the time course available for analyzing the imaging data.

All imaging procedures quantify a parameter for a unit of three-dimensional space within the individual. The measures of three-dimensional space acquired in the imaging techniques are called "voxels." Through quantification the values of the voxels are then arranged in an array to represent their spatial relationship within the living brain. These data are then typically transformed into an image displayed as a plane in two-dimensional space.

Neuroimaging Techniques

Computed Tomography (CT)

Modern brain imaging was revolutionized in the 1970s with the introduction of computerized X-ray tomography. This

was one of the first widely practiced and accessible neuroimaging techniques that allowed investigation of the living brain. In CT, multiple X-ray beams of radiation are projected through the object of interest (e.g., brain) and the intensity of the emerging radiation is measured by detectors. Intravenous contrast agents may be used with CT to increase its sensitivity in detecting pathology. CT is particularly good at detecting abnormalities in the bone, calcifications, and acute bleeding. Limitations include exposure to radiation, poor differentiation between soft tissue densities, and circumscribed views of the person being scanned. CT is used primarily in clinical settings.

Magnetic Resonance Imaging (MRI)

In MRI, radio waves immerse a person centered in a magnetic field with the signals absorbed and re-emitted in proportion to the mobile hydrogen ion concentration in the tissue of the person. The absorbed energy is detected by a radio receiver when it is re-emitted. MRI has evolved rapidly and is increasingly used for both clinical and research applications into general cognitive functioning and pathology. The technique is noninvasive (e.g., does not expose one to radiation) and produces images with excellent spatial and temporal resolution. Structural MRI of the brain produces images of brain anatomy, whereas functional MRI (fMRI) produces indirect measures of brain activity through the study of changes in blood flow and blood oxygenation. FMRI uses standard MRI scanners with fast imaging techniques and works on the principle that focal changes in neuronal activity tend to be coupled with changes in brain blood flow and blood volume. FMRI is becoming widely available, but is primarily a research tool. Limitations to MRI include occasional claustrophobia, prohibitive use of metal implants in users, and sensitivity to motion artifacts.

Positron Emission Tomography (PET) and Single Photon Emission Computed Tomography (SPECT or SPET)

In both PET and SPECT a radioactive tracer is injected or inhaled into the blood stream. The tracer is distributed in the brain and emits a photon signal that is detected by the scanner. The techniques measure the regional distribution of radioactive activity, which, depending on the labeled tracer, can measure glucose metabolism, blood flow, or the distribution or density of a receptor. Blood flow and metabolism are typically coupled and are used as a measure of neural activity. A variety of tracers are available in PET, each measuring different parameters (e.g., regional cerebral blood flow, glucose metabolism, or receptor distribution). PET is increasingly used as an advanced technique to identify pathology (e.g., tumors and neuronal degeneration). Water containing oxygen 15 is considered the best and most widely used PET tracer for assessing blood flow in cognitive studies. This tracer is ideally suited for this purpose because its short half-life (2 minutes) allows research subjects to be scanned several times in different cognitive states or doing various tasks. With all techniques involving ionizing radiation, however, there are limits on the total acceptable amount of radiation exposure for the subject.

Future Directions in Neuroimaging

Several other techniques are also being used to reveal how the brain works. Many of these techniques will be used with those described above. Magnetoencephalography (MEG) and electroencephalography (EEG) are tools that can measure neuronal function with submillisecond temporal resolution—which is preferable for studying many cognitive processes. MEG is particularly promising because it can be used to visualize the time course of regions of activation as they become activated during a task. MEG measures signals proportional to electroencephalographic waves emanating from brain electrical activity. Magnetic Resonance Spectroscopy is a rapidly expanding, noninvasive technique that can measure the chemical composition of proton, phosphorus, and carbon-based molecules. The technique generates plots representing the chemical composition of a brain region. Diffusion tensor imaging (DTI) is another rather novel technique that makes use of the ability of MRI to measure the movement and diffusion of water. In certain brain tissues, such as the white matter, this diffusion is along the white matter tracts; thus, the technique can be used to map the presence, direction, and thickness of cerebral white matter fibers. DTI is used in clinical applications to assess the degeneration or remodeling of tissue structures associated with disease. It is used in research applications to study the relationship between structure and function of tissue electrophysiology and biomechanics. Finally, transcranial magnetic stimulation is another tool for the noninvasive manipulation of brain activity that may be combined with traditional imaging tools to help determine whether a particular region is critical for performing a cognitive or motor operation.

NEUROLINGUISTICS

Broadly defined, neurolinguistics is a theory of language and brain. A formal theory of neurolinguistics is developing through interaction in the fields of neurology, psychology, and linguistics. Larnendella urged a simultaneous integration of three distinct perspectives in the formal theory of language and brain: *overt speech and language behavior,*

covert neuroanatomy and neurophysiology, and the *functional organization of speech and language systems* as a contingent reality. He emphasized the need to incorporate into neurolinguistic theory implications of nonverbal communication systems of human behavior, of cultural and individual variables developed through environmental modification, and of cognitive information processing and a theory of human cognition.

Neurolinguistics may be described as a study of how information is received through the senses, processed in the neurons and neural pathways of the brain (including the language areas), and expressed in language and behaviors. The most salient sensory modalities for information processing into language are the visual, auditory, and kinesthetic modalities. Optimally, information is received and expressed in all channels with consistency and equal efficiency.

Information processing is concerned with two types of symbols: *theoretical,* related to language, and *qualitative.* Processing the different types of symbols is believed to depend on functions occurring within the left and right hemispheres of the brain. Theoretical symbols such as visual linguistic elements (e.g., the written word), auditory linguistic elements (e.g., the spoken word), visual quantitative elements (e.g., written numbers), and auditory quantitative elements (e.g., spoken numbers) are processed primarily in the left hemisphere of the brain.

Qualitative symbols of a sensory nature, such as sounds, taste, or pictures, are associated with cultural codes or the meanings received from nonverbal expressions, role playing, social distance, or time constraints, and are processed primarily in the right side of the brain. The bilateral symmetry of the brain provides that sights and sounds bringing in information from the external environment will be processed by both hemispheres together.

Neurolinguistic evidence is contributing to the understanding of communication, cognition, culture, and their practical applications. In addition to the study of disordered brain function, experimental techniques have been applied to speech and language processing in individuals who are considered normal. Research has indicated varying responses of individuals who are considered normal in the sensory modalities of vision and audition.

Electrophysiological experiments using auditory and visual stimuli show that auditory responses are significantly greater in the left hemisphere, and visual responses are significantly greater in the right hemisphere.

The right ear outperforms the left ear in hearing and identifying competing digits—a reflection of left-brain dominance for language. A clear left-ear advantage was found for melodies and environmental sounds. The left ear has direct access to the right hemisphere, and the right brain is dominant for music, chords, and nonverbal sounds.

Individuals tend to look up and away when a question has been posed and the answer must be retrieved. The same neurological pathways and structures seem to be used for both external stimulation in a given sensory modality and internal fantasies in that same modality.

Human beings who are considered normal are all endowed with essentially equivalent sensory organs and structures, both anatomically and physiologically. Each individual learns to depend on one sensory system or another as a means of perceiving and understanding the world. The Sensory Modality Checklist assesses an individual's preferred sensory modality for learning and self-expression.

Neuro-Linguistic Programming (NLP) is the study of the structure of subjective experience, or how individuals perceive and understand the world. Neuro-Linguistic Programming is a trademark name for a model of techniques and strategies for interpersonal communication based on some elements of transformational grammar and on the identification of preferred sensory representations for learning and self-expression.

Bandler and Grinder identified the process indicating that the predicates people use are representative of their preferred sensory modalities. An individual who highly values the visual system uses visual process words and predicates (verbs, adjectives, adverbs) such as "clear," "bright," "see," and "perspective."

Bandler and Grinder also describe the nonverbal and physiological cues that people unconsciously use. Eye movements, breathing patterns, body postures, and body types give clues to an individual's preferred sensory modality.

N. A. Haynie

NEUROMUSCULAR DISORDERS

Neuromuscular disorders generally refer to disease processes that affect motor neurons, including axons and the innervation of the motor neurons with muscle fibers. A great many neuromuscular disorders are inherited, although it is common to find no genetic link in some cases. At the onset of symptoms, neuromuscular disease typically manifests itself as an asymmetrical weakness with intact sensation. As the disorder progresses, the symmetry of wasting becomes apparent, with each side of the body manifesting similar rates of muscle atrophy.

Neuromuscular disorders may be most easily characterized in terms of level and degree of motor neuron involvement. Disorders involving the upper motor neuron tracts, such as progressive spastic bulbar paralysis, and demyelinating diseases, such as multiple sclerosis (MS) and amyotrophic lateral sclerosis (ALS), cause bulbar paralysis. Symptoms typically include difficulty speaking and swallowing, and respiratory failure.

MS, a demyelination disorder with axonal degeneration, is the most common disabling neurological condition observed in young adults. Symptom onset typically occurs in

the fourth decade of life and is more common in women. It appears to be the result of genetic risk in combination with environmental factors, as the disorder is more common in individuals who have lived in the more Northern and Southern latitudes for at least 15 years and who have family members with MS. There are four types of MS, with the former types being more common than the latter: relapsing-remitting, secondary progressive, primary progressive, and progressive relapsing. Symptoms of MS include ataxia, sensory disturbances, trigeminal neuralgia, tremor, muscle spasticity, ocular impairments, paralysis, generalized fatigue, depression, and impaired concentration and memory. Dementia is also present in some cases.

ALS, also known as Lou Gehrig's disease, often affects both the upper and lower motor neuron tracts. Approximately 5 to 10% of individuals with ALS have an autosomal dominant inheritance pattern linked to chromosome 21. Onset of symptoms is typically in middle adulthood, and is characterized by muscle weakness and atrophy accompanied by subcutaneous muscle twitching in one arm or leg. The symptoms spread across the rest of the body, including the face, pharynx, and tongue, resulting in flaccid quadriplegia, and atrophic and areflexic muscles. Death typically results from respiratory complications and occurs 2 to 4 years after symptom onset. ALS typically has no cognitive component, although some individuals exhibit dementia, so individuals with the disorder are usually aware of their symptoms and can make choices about end-of-life decisions, including the use of respiratory ventilators.

Although it has been eliminated as a wild virus, poliomyelitis is a virus that causes an infection in the anterior horn cells of the spinal cord (motor neurons) and lower brain stem. Polio does not affect cognitive functioning, but results in asymmetric paralysis, muscle fasiculations, and the absence of deep tendon reflexes.

Nonviral neuromuscular diseases occurring with some frequency include myasthenia gravis, myotonic dystrophy, and Duchenne's muscular dystrophy. Myasthenia gravis is a neuromuscular junction disorder caused by an autoimmune response that blocks the nicotinic receptors in the extraocular and facial muscles and is associated with thymus gland abnormalities. The disorder, which typically affects young women and older men, results in fluxuating and asymmetric muscle weakness, but causes no cognitive symptoms. The symptoms of myasthenia gravis include facial and neck muscle weakness, difficulty controlling neck and shoulder muscles, difficulty swallowing, and poor respiratory functioning. In severe cases, this disorder may result in quadriplegia and respiratory distress.

Myotonic dystrophy is a commonly occurring neuromuscular disorder in adults, with symptom onset typically in the third decade of life. Males and females are equally affected as this disorder is carried on chromosome 19. Symptoms appear to have an earlier onset and are more severe when the disorder is inherited from the father. Myotonic dystrophy is also subject to genetic amplification such that the symptoms are more severe and have an earlier onset in successive generations. Early symptoms include facial and distal dystrophy with myotonia, such that following voluntary effort, muscles have prolonged and uncontrolled contractions. Disease progression is slow and variable. Later symptoms can include endocrine system failure, cataracts, cardiac symptoms, personality change, dementia, and limited intelligence.

Duchenne's muscular dystrophy is the most frequently occurring neuromuscular disorder in children. The disorder is sex-linked, with symptoms displayed only in males, but females carry the genetic defect asymptomatically. The symptoms are caused by a failure to produce dystrophin, a muscle-cell membrane protein. First evidence of the disorder is difficulty standing and walking with pseudohypertrophy in the calf muscles during childhood. Gower's sign, wherein boys with Duchenne's appear to "climb their own legs," is highly diagnostic. Progression of the disorder is relatively rapid and by early adolescence, boys with Duchenne's typically require a wheelchair. The disorder is fatal, with death typically resulting from respiratory insufficiency in the late adolescent or young adult years. Duchenne's is sometimes accompanied by mental retardation.

Other, less common motor neuron diseases include Werdnig-Hoffman's disease (hereditary ALS-like symptoms identified in infants), Kugelberg-Welander disease (hereditary ALS-like symptoms identified in children), Oppenheim's disease, progressive neuropathic muscular atrophy, and Dejerine-Scottas' disease. Age at onset, disease progression rate, and years of survival vary.

There are no cures for neuromuscular disorders, although the utility of gene therapies is being investigated in some cases. Treatment of symptoms associated with neuromuscular disorders focuses on avoiding infection and controlling spasticity. Psychological intervention should center around counseling and the maintenance of patient support mechanisms.

NEURONAL CELL BODY

As a single cell, the neuron is highly specialized in the extent of its regionalization, that is, its structural and functional compartmentalization. Three distinct regions or

compartments can be identified in a typical neuron: dendrites, cell body, and axons. The cell body plays two principle roles in the life of a neuron: supporting most of its macromolecular synthesis and serving as the site at which input signals are integrated to determine output signals.

The cell body, also called the neuronal soma, is defined as the compartment of the neuron containing the cell nucleus. In addition to the nucleus, the cell body is the compartment most like a typical animal cell in that it also contains ribosomes, endoplasmic reticulum, the Golgi apparatus, and the other cellular organelles involved in the synthesis, processing, and delivery of macromolecules throughout the cell, for example proteins and membrane components. Axons and dendrites are both narrow extensions of cytoplasm that grow from the cell body during early embryonic development. The synthetic capacity of these other compartments is much reduced compared to the cell body and, in the case of axons, is nearly absent. In addition to lacking synthetic machinery, the extreme length of many neural axons means that its compartment typically has the majority of the cytoplasmic mass of the cell. Thus, the axon grows and is maintained only by being supplied with proteins and membrane components from the relatively smaller mass of its cell body. Disruption in the synthesis, degradation, processing, or subsequent delivery to the axon of macromolecules underlies a variety of neuronal pathologies. In Alzheimer's disease, for example, inappropriate processing of a normal integral membrane protein of brain neurons produces short protein fragments that aggregate to form an insoluble precipitate. This, in turn, leads to neuronal cell death and progressive loss of cognitive function.

In addition to their differences in synthetic function, the three compartments of a neuron differ also in their electrical signaling functions as part of a system of neurons. Dendrites are the input side of neurons, receiving various chemical information from other cells, typically other neurons, and converting it into local electrical signals. The cell body receives this electrical input, both stimulatory and inhibitory, from its entire dendritic arbor and integrates it to produce a net stimulus. This overall stimulus within the cell body then determines the informational electrical output of a neuron, which propagates along the very long and narrow axonal projection. The classic view of this process of integration is that the cell body is the site of essentially passive summing of the various inhibitory and stimulatory inputs to arrive at a net stimulation or inhibition of output, that is, initiation or suppression of action potentials. More recent evidence suggests that the cell body may actively amplify or decrease input signals as part of its integration function determining output.

Structurally, the cell body of neurons is usually a compact, rounded mass of cytoplasm that contrasts with the narrow tapering arbor of dendritic branches, as well as with the exceptionally elongated axonal process. In general, neuronal cell bodies tend to occur in identifiable aggregates within the nervous system at which neuron-to-neuron signaling occurs. In other words, cell bodies and their associated synapses tend to occur in clumps. In the brain, a region with a large number of cell bodies is called a *nucleus.* For example, the lateral geniculate nucleus is the brain region in which visual processing first occurs after the eyes. Outside the brain and spinal cord, aggregates of neuronal cell bodies are called *ganglia.* For example, dorsal root ganglia are found just outside the spinal cord and are aggregates of the cell bodies of sensory neurons from the skin and muscle that relay information about these peripheral tissues to the central nervous system.

NEUROPSYCHOLOGICAL DEVELOPMENT

The growth of the brain and nervous system can be described as if it were a series of changes that occur at particular ages. Although some changes are rapid and dramatic, others are more gradual. Regardless of the rapidity of change, however, these changes generally occur in a fixed sequence.

The first stage of brain development is *cell migration,* during which nerve cells are formed in the inner or ventricular lining of the brain. After formation they migrate from the inner lining through the layers that already exist, to eventually form a new outer layer. This means that structures such as the cortex actually mature from the inner to the outer surfaces.

During the cell migration stage, *axonal growth* manifests itself, as axons begin to sprout from the migrating cells. Axons are the elongated neural process that carries information away from the cell body to be received by other cells down the line. Each axon has a specific target that it must reach if the neuron is to be functional. How each axon locates its target is still an unsolved question.

The *growth of dendrites* is the next major change in the system. This growth does not begin until after the cell reaches its final location after migration. At some stages of dendritic growth there appears to be an overabundance of dendritic branches. Some of these excess or unused branches are eventually lost in a process referred to as "pruning," which is actually a loss of neural material.

The time course of *synapse formation* has been mapped in detail for primates. Synapses begins to form about 2 months before birth and grow rapidly for several months. In humans, synaptic growth is known to continue for at least 2 years after birth. There is some suggestion that experience may affect the survival of synapses. This is based upon the fact that, between about 2 and 16 years of age,

there is actually a loss of about 50% of the synapses. One speculation is that only the regularly used synapses survive, with unused synapses disappearing through a process sometimes referred to as "shedding."

While it has been generally believed that neural development is completed after about 2 years of age, in fact growth continues well beyond this point. There is even some suggestion that brain growth occurs at irregular intervals, called "growth spurts" (Banich, 1997). Such spurts occur at around 3 to 18 months and at 2 to 4, 6 to 8, 10 to 12, and 14 to 16 years of age. Except for the first (rather long) spurt, during which brain weight increases by about 30%, each subsequent growth spurt increases brain mass by 5 to 10%. It is tempting to try to correlate these growth spurts with overt changes in development. Thus it may be significant that the first four episodes of rapid brain growth seem to coincide with Piaget's four principal stages of cognitive development.

Other changes in the neural system continue well beyond adolescence. An important factor in the later stages of neuropsychological development is cell loss. For instance, the area of the occipital cortex that receives projections from the fovea of the eye contains about 46 million neurons per gram of tissue in a 20-year-old. In an 80-year-old, however, the neuronal density is reduced by nearly one half, to only 24 million neurons per gram of tissue. This cell loss is believed to account for some of the loss of visual acuity in older individuals (Coren, Ward, & Enns, 1999). Similar losses in other areas of the brain might also be expected to affect normal functioning.

Brain size and mass can also be affected by experience. Exposure to a stimulus rich environment seems to increase brain size, especially in the neocortex. Such enriched stimulus exposure seems to increase the number of dendrites and synapses, especially if the enriched experience occurs early in life. Furthermore, animals with larger brains as a result of more varied experience seem to perform better on a number of behavioral tasks, including those involving memory and learning. In contrast, animals reared from birth with restricted sensory inputs, such as no light to the eyes, possess a reduced number of functioning cells and more abnormal neurons in the appropriate sections of the cortex (e.g., Atkinson, 2000).

Environmental effects in the form of traumas that affect the developing fetus—such as toxic agents, mechanical injury, chemical imbalances, a stressful birth, or a difficult pregnancy—can cause both subtle and dramatic disturbances in neural development. In some cases, changes in function ("soft signs") are used to determine the likelihood that there is some form of damage or disruption in neurological development that cannot specifically be seen in physiological examinations, but must be inferred from behavioral changes.

Generally speaking, neuropsychological development follows a fixed sequence of stages with an initial developmental predisposition, period of environmental vulnerability, period of plasticity, and finally fixed functional properties.

NEUROPSYCHOLOGY

Origins of the Term Neuropsychology

Historically, the field of neuropsychology was derived not only from the discipline of psychology, but also from the various related disciplines within the traditional professions of medicine, education, and law (Meier, 1997). The term *neuropsychology* is a combination of the word *neurology,* which is defined as a branch of medicine that deals with the nervous system and its disorders, and *psychology,* which is defined as the study of behavior or the mind (Finger, 1994). One of the first people to combine the words neurology and psychology into neuropsychology was Kurt Goldstein (Frommer & Smith, 1988) in his book *The Organism* (1939). Neuropsychology today is used to describe a field of psychology that principally circumscribes the identification, quantification, and description of changes in behavior that relate to the structural and cognitive integrity of the brain (Golden, Zillmer, & Spiers, 1992).

The Neuropsychologist as a Professional

Most individuals who call themselves neuropsychologists are professionals involved with assessing and treating human patients (i.e., clinical neuropsychology) (Finger, 1994). A majority of neuropsychologists in practice work with either psychiatric or neuropsychological populations in a variety of settings: private practice, university-based medical centers, psychiatric hospitals, general community hospitals, mental health centers, university psychology departments, and prisons (Golden, 1983). Neuropsychologists are involved in specifying the nature of brain-related disorders and applying this information to rehabilitation and education. In order to achieve this, the clinical neuropsychologist is required to establish a comprehensive database of historical and current general medical, surgical, neurological, neuroradiological, pharmacological, developmental, and psychosocial factors underlying the presenting problem (Meier, 1997).

Diagnosis in Neuropsychology

One of the major questions facing neuropsychologists is the differentiation of brain damage from the major psychiatric disorders (Golden, 1983). The reason for the difficulty in differentiation lies in the fact that the range of psychiatric disorders is broad and involves elements of cognitive impairment commonly seen in brain injury. The area of diagnosis for the neuropsychologist includes three subareas. The first subarea involves the identification of the presence of a brain injury in which a differentiation must be made between disorders caused by emotional problems and those caused by injury to the function of the brain. The second subarea involves the specification of the nature of the deficit caused by brain damage, including localizing the injury to specific areas of the brain. The third subarea includes the identification of the underlying process or underlying cognitive disorder (Golden, 1983).

Neuropsychological Assessment

The primary goal of assessment in neuropsychology is to address the relevant neurobehavioral aspects of higher psychological functioning that are considered to be central to understanding the cognitive strengths and deficits of the individual (Meier, 1997). In neurodiagnostic settings, there is an emphasis on the search for dysfunctional aspects of an individual's cognition and behavior that aid in diagnosis of the particular lesion, disease, syndrome, or condition (Golden, Zillmer, & Spiers, 1992). In addition, neuropsychological assessments can also serve as a baseline for a patient's abilities so that a course of recovery or decline in a patient can be evaluated (Golden, Zillmer, & Spiers, 1992).

Neuropsychological assessments are typically organized into standardized or flexible batteries. Standardized batteries are those in which patients take all tests in a given battery. Some examples of standardized neuropsychological batteries include the Halstead-Reitan and the Luria Nebraska test batteries. Both batteries are composed of an established set of tests that assess those neurocognitive functions that are susceptible to disruption from neurologic impairment, including those sustained after head injury (Smith, Barth, Diamond, & Giuliano, 1998). Flexible neuropsychological batteries are those in which the neuropsychologist creates a customized battery of specific tests or modifies a basic battery based on individual patient issues and history (Smith et al., 1998).

Treatment Evaluation

Neuropsychologists may use tests to evaluate the effectiveness of interventions with a client after brain injury. Such interventions may include medical treatment (e.g., surgery for chronic epilepsy), speech therapy, occupational therapy, physical therapy, or whether a particular drug makes a patient better or worse in terms of neuropsychological functioning (Golden, 1983). For instance, a study by Goldberg et al. (1982) found significant improvement in memory after drug treatment (Hanlon, 1994). These studies aid in documenting and evaluating the effects and value of treatment.

Rehabilitation

The primary objective of neuropsychological rehabilitation is to improve the quality of life of individuals who have sustained neurological insult which may involve cognitive, behavioral, emotional, and social factors (Hanlon, 1994). Neuropsychological assessment can serve as a first step in developing a rehabilitation program for a patient because it allows the clinician to fully document the details of the patient's strengths and weaknesses. Documentation integrated with an understanding of brain function allows the clinician to understand the behavioral, cognitive, and emotional effects of an injury (Golden, Zillmer, & Spiers, 1992).

Hanlon (1994) described four primary approaches to cognitive rehabilitation that are currently practiced: (1) the direct retraining approach that involves the use of repetitive drills and exercises; (2) the substitution-transfer model, in which visual imagery is used to facilitate verbal retention, verbal mediation, and elaboration to compensate for visual memory dysfunction; (3) the functional compensation and adaptation model, which involves the use of any and all strategies, techniques, devices, and adaptive equipment that enable the patient to perform tasks that can no longer be performed in a conventional manner; and (4) the behavioral approach, which is based on the principles of learning theory and behavior.

Future Trends in Neuropsychology

The field of neuropsychology continues to expand. Kay and Starbuck (1997) have noted that the relatively low cost of personal computers and the potential of having computers perform labor-intensive scoring and test administration procedures may explain the popularity of computer applications in neuropsychological assessment. However, they also add that computerized testing appears to have had only minimal impact on the field of neuropsychology, probably because of a general resistance to novel methods or to the lack of human-to-human contact.

NEUROTRANSMITTER RELEASE

Neurons can communicate with each other by direct ion fluxes at "electrical or electrotonic synapses," but more commonly do so by releasing chemical messenger molecules, termed neurotransmitters, from their terminals at "chemical synapses." Depending on the type of neuron or neuroendocrine cell, neurotransmitters are stored either in membrane-bound, electron-lucent synaptic vesicles approximately 50 nm in diameter, or in larger vesicles with dense cores. They are released by appropriate stimuli into the extracellular space, evoking a response in neighboring cells by binding to membrane receptors. They are subsequently eliminated by diffusion, by degradation, or by uptake into presynaptic terminals or neighboring glial cells.

Bernard Katz and his collaborators in the early 1950s were the first to recognize that the end plate potentials recorded electrophysiologically at neuromuscular junctions were the sum of many "miniature" end plate potentials produced simultaneously, each of which represented the release from a single vesicle of a "quantum" comprised of several hundred molecules of the neurotransmitter acetylcholine, ACh. Many other molecules have since been recognized to fulfill the four essential criteria of neurotransmitters, which are: (1) neuronal synthesis, (2) presence in the axon terminal, (3) release from terminals in response to stimulation, and (4) production of a biological effect when applied exogenously to synapses.

Neurotransmitters can be classified according to their chemical structure: *biogenic amines,* principally ACh and monoamines, including the indoleamine, serotonin (5-hydroxytryptamine), and the catecholamines, dopamine, noradrenaline, and adrenaline; *amino acids,* including GABA (γ aminobutyric acid), glutamic acid, and glycine; *peptides,* such as endogenous opioids and substance P; and *neurotransmitters with no chemical similarities,* such as nitric oxide and adenosine.

Neurotransmitters are termed "fast" (e.g., ACh, GABA, etc.) or "slow" (e.g., peptides) and most are rapidly eliminated after release. Peptides, however, represent an exception and can act over long periods far from their release sites. Neurotransmitters are released from neurons in response to the arrival of an action potential or the interaction of specific ligands with membrane receptors, stimuli that trigger opening of voltage-dependent Ca^{2+} channels, allowing Ca^{2+} to enter the nerve terminal. Release kinetics and Ca^{2+} requirements vary considerably between different types of neuron and neuroendocrine cells and also for different types of neurotransmitter. Thus, release from small synaptic vesicles in neurons occurs less than a millisecond after stimulation, while in cultured pheochromocytoma cells the delay can be 200 ms and this increases to up to one second for adrenaline and noradrenaline secretion from large (2 to 500nm diameter) secretory granules in adrenal medullary chromaffin cells. In addition, Ca^{2+} influx at nerve terminals, and thereby neurotransmitter release, can be modulated via presynaptic membrane receptors, such as GABA receptors.

Neurotransmitters are classically considered to be released by a multistep process involving translocation of neurotransmitter storage vesicles to synaptic membranes; vesicle docking at active membrane sites; Ca^{2+}-triggered fusion of vesicle membranes with synaptic membranes and exocytosis of vesicle contents into the extracellular space; and vesicle endocytosis involving clathrin-coated vesicles.

In resting neurons, most synaptic vesicles accumulate in the distal cytoplasm of presynaptic terminals in reserve pools, linked to F-actin by the protein synapsin. Stimulation causes the Ca^{2+} concentration to rise near Ca^{2+} channels, provoking synapsin phosphorylation by specific kinases, which permits vesicles to dissociate from the cytoskeleton and translocate to active synaptic membrane sites. Vesicle docking at these sites is mediated by interactions between highly conserved proteins also implicated in constitutive secretion and intracellular trafficking. These include both soluble cytosolic proteins, such as NSF (**N**-ethylmaleimide **S**oluble **F**actor) and **S**oluble **N**SF **A**ttachment **P**roteins (SNAPs), and membrane-bound SNARE (**S**oluble **N**SF **A**ttachment **Re**ceptor) proteins. Synapto-

brevin and synaptotagmin have been identified as vesicle membrane SNAREs, and SNAP-25 and syntaxin as synaptic membrane SNAREs. Docking involves formation of NSF/SNAP/SNARE complexes and depends on GTP and small G-proteins. Subsequent Ca^{2+}-dependent ATP hydrolysis enables synaptotagmin and synaptobrevin to dissociate from the complex, permitting vesicles to move even closer to the membrane and fuse with it. This Ca^{2+}-dependent step involves the opening of a fusion pore, in which the vesicle protein synaptophysin may participate, allowing the neurotransmitter inside the vesicle to escape into the extracellular synaptic space. Other vesicular proteins, including cysteine string proteins and syntaxin, may facilitate vesicular association with Ca^{2+} channels, thus helping to prime the transmitter release cascade.

Two alternative mechanisms have been proposed for neurotransmitter release. In the first, the "kiss and run" theory, synaptic vesicles undergo rapid and reversible interactions with the membrane which stop short of complete fusion, but which allow variable amounts of neurotransmitter to diffuse out. This mechanism thus involves the transient formation of a gate with channel properties, which is equivalent to the initial step in vesicle/synaptic membrane fusion in the classical view of neurotransmission. A second contrasting hypothesis abandons the notion of vesicle fusion and suggests that a 200 kDa "gate" protein, termed a "mediatophore," located in the nerve terminal membrane, is alone sufficient for the Ca^{2+}-dependent release step. It estimates that the brief opening of around 10 gate proteins would allow quantal release of neurotransmitter and at the same time generate miniature end plate potentials.

It seems unlikely that neurotransmitters are released by strictly identical mechanisms in all neurons and related cells, because not all proteins thought to be implicated in exocytosis have been detected in all neurons. The markedly different release kinetics for neuroendocrine cells and neurons and for different types of synapses also suggest that regulation differs between cell types. Photoreceptor retinal bipolar cells and hair cells of the inner ear illustrate this dramatically. They possess special "ribbon" synapses, which release neurotransmitters from vesicles according to a graded response depending on the extent of their membrane depolarization. These synapses are specifically adapted to rapid, almost continuous, firing, in contrast to the action potential-triggered periodic bursts of activity from conventional synapses. Thus, in such synapses Ca^{2+} channels differ from those in other neurons by their resistance to inactivation, and translocation of vesicles to active membrane sites is not controlled by synapsin, as in conventional terminals, but occurs by a distinct, more efficient mechanism to satisfy the high firing rate.

NEUROTRANSMITTERS

A neurotransmitter is a chemical substance that carries a "message" from the terminal bouton of one nerve cell or neuron across a tiny gap (synapse) to receptor sites on another neuron. Neurotransmitters are, in general, synthesized in the neuron's cell body and stored in tiny sacs called synaptic vesicles.

Nobel Prize winner Otto Loewi is credited with demonstrating synaptic transmission's chemical nature in 1920. Loewi isolated a frog heart with an attached vagus nerve. Stimulating the nerve caused the heart's rate to decrease; when Loewi extracted some of the fluid around the heart and applied it to an unstimulated second heart, the second heart's rate slowed as well. Loewi concluded that stimulating the nerve to the first heart had released a chemical at the synapse between the vagus nerve and the heart, and this chemical had transported the message to the heart to slow down. Because he had stimulated the vagus nerve, Loewi called the mysterious chemical "Vagusstoff." It was later discovered that Vagusstoff was acetylcholine (ACh).

When a neurotransmitter such as ACh diffuses across the synapse, it binds to specific postsynaptic receptors to produce either a local excitatory effect or an inhibitory effect. Whether the postsynaptic neuron passes on the message by producing an action potential depends on the sum of the influences it receives from presynaptic neurons.

A neurotransmitter that remained in the synapse for any length of time would limit the number of messages that could be passed from one neuron to another. Thus, the neurotransmitter is rapidly inactivated almost from the moment of its release. One common method of inactivation is called reuptake, a process through which the neurotransmitter is taken back into the presynaptic neuron from which it was released.

The second major inactivation mechanism is used on ACh and on neuropeptide neurotransmitters and is called enzymatic degradation. In the former case, acetylcholinesterase (AChE) breaks the ACh molecule into two parts, neither of which produces the effect of ACh. Neuropeptides, once released, are degraded by peptidase. Diffusion, the drifting away of neurotransmitter molecules from the synapse, is another inactivation method that occurs with all neurotransmitters.

The brain uses as many as 100 neurotransmitters. For many years, it was believed that each neuron released only one particular neurotransmitter from all its nerve terminals. We now know that many if not most neurons release two or three transmitters, and some may release as many as five or six.

The three major categories of neurotransmitters are biogenic amines, amino acids, and peptides. One biogenic amine—ACh—is found in the brain and spinal cord, and is also the chemical that carries messages from the motor nerves to the skeletal muscles. Other important biogenic

amines include dopamine, norepinephrine, epinephrine, and serotonin.

Dopamine is importantly implicated in two major brain disorders: schizophrenia and Parkinson's disease. In Parkinson's disease, cells die in a brain area called the substantia nigra (Latin for "black substance"). In the course of the disease, the "black substance" actually becomes white because of the loss of dopamine-producing cells. Nigral cells normally project dopamine to the neostriatum, which controls motor activities. Without the neurotransmitter, the afflicted individual begins to develop characteristic symptoms such as tremor at rest, rigidity, and bradykinesia. Replacement therapy—supplying drugs to increase the amount of dopamine in the brain (for example, L-dopa)—may work temporarily, but unfortunately, the disease is progressive.

Schizophrenia is also associated with defects in the dopamine system, in this case by increased activity. Major antipsychotic drugs, both typical—such as chlorpromazine (Thorazine)—and atypical—such as resperidone (Risperdal)—block subtypes of dopamine receptors.

Norepinephrine (also called noradrenalin) is the neurotransmitter at the post-ganglionic sympathetic nervous system, and is also found in the brain. Decreased norepinephrine and/or serotonin activity in the brain are thought to contribute to depression. Most drugs used to treat depression increase the release of norepinephrine, serotonin, or both.

Gamma-aminobutyric acid (GABA) is an example of an amino acid neurotransmitter. GABA is the most common inhibitory neurotransmitter in the brain, and the destruction of GABA neurons in a major motor system (the basal ganglia) occurs in Huntington's disease. Symptoms of Huntington's disease include involuntary movements. Antianxiety drugs such as diazepam (Valium) and alprazolam (Xanax) act by stimulating GABA receptors. Other amino acid neurotransmitters include glutamate (the most common excitatory neurotransmitter in the brain), glycine, and aspartate.

The peptide neurotransmitters include the "endorphins," or "endogenous morphine-like substances." Because opiates such as morphine and heroin are so addictive, brain researchers suspected that there were receptors for the opiates in the brain. In 1973, such receptors were found, which led to the further discovery of naturally occurring neurotransmitters with opiate-like properties, which induce analgesia and euphoria. Some functions in which the endogenous opiates have been implicated include the placebo effect, runner's high, and pain relief from acupuncture (but not from hypnotically induced analgesia). Other examples of peptide neurotransmitters include substance P (involved in pain perception), oxytocin (responsible for labor pains), and cholecystokinin (involved in hunger satiety).

In addition to the categories of neurotransmitters discussed, there is a newly discovered group of neurotransmitters that appear to break all the "rules" governing the actions of neurotransmitters. These are soluble gases that are made in all parts of neurons, are released as soon as they are manufactured, and do not affect postsynaptic receptors. The soluble gases identified at this time are nitric oxide and carbon monoxide. Nitric oxide is apparently involved in such disparate functions as penile erection, dilation of blood vessels in areas of the brain that are metabolically active, and learning.

NICOTINE

Nicotine is a pale yellow, highly toxic liquid contained in the leaves of several species of plants. Commercially, nicotine is extracted from dried *Nicotiana tabacum* leaves and used for making insecticides (nicotine sulfate) or tobacco products (Benowitz, 1998). Nicotine is extremely poisonous and can cause respiratory failure, convulsions, nervous system paralysis, and death if consumed in a single dose of 50 mg or more.

Nicotine is typically found in tobacco products such as cigarettes, cigars, snuff, chew, and pipes as well as in insecticides such as Black Leaf (40 percent nicotine sulfate; Benowitz, 1998). Most tobacco products, such as cigarettes, contain 10 milligrams or more of nicotine content (American Cancer Society [ACS], 1997). However, when smoked, a single cigarette delivers approximately 1 to 3 mg of nicotine, as well as 4,000 other chemicals, to the nose, mouth, and primarily to the lungs, where nicotine is quickly assimilated through cell membranes into the pulmonary capillary blood flow (Grunberg, 1999). After inhaling, nicotine is transferred to the brain within approximately 10 seconds from the first puff (National Institute on Drug Abuse [NIDA] 1998).

Because smoking so quickly transports nicotine to the brain, cigarettes provide an efficient and consistent "drug-delivery system" (Hurt & Robertson, 1998; NIDA, 1998). Nicotine affects the mesolimbic system, or the pleasure center of the brain, creating increased levels of dopamine, a neurotransmitter essential to the functioning of the central nervous system and emotion regulation (Brauthar, 1995; Pich, Pagliusi, & Tessari, 1997). An increase of dopamine elicits feelings of euphoria and has been linked to the addictive process. Nicotine also elicits pleasurable feelings such as relaxation, stimulation, and increased attention, reinforcing continued use (Corrigall, Franklin, Coen, & Clarke, 1992; Hurt & Robertson, 1998; Ovid & Pomerleau, 1992).

Because nicotine is so addictive, as well as toxic, tobacco

use is a primary health concern. Cigarette smoking contributes to approximately 400,000 deaths annually in the United States and the majority of these deaths are directly attributable to cancer (ACS, 1999; Peto, Lopez, Boreham, Thur, & Heath, 1992). Nicotine stimulates the division of small cell carcinomas, a cancer cell line, by several hundred percent. As a result, tobacco use is associated with many types of cancers, such as lung, larynx, esophageal, bladder, pancreatic, kidney, and colon cancers (ACS, 1996; Centers for Disease Control [CDC], 1993a). Tobacco use also leads to an increase in heart disease as well as respiratory diseases such as emphysema and chronic bronchitis (CDC, 1993a). Additionally, women who smoke during pregnancy have an increased risk of spontaneous abortion, preterm birth rates, low birth weights, and fetal or infant death (DiFranza & Lew, 1995; Slotkin, 1998).

Effective methods to assist people in quitting smoking can clearly reduce the risk of cancer and health hazards from smoking (CDC, 1993a). Recent advances in the treatment of nicotine dependence offer a variety of options such as behavior modification programs, antidepressants (Zyban), nicotine replacement therapies such as the patch (Nicoderm CQ, Nicotrol, Habitrol, etc.) or nicotine gum (Nicorette), as well as nasal spray (Nicotrol NS) (Henningfield, 1995; Rose, 1996). With the variety of smoking-cessation treatments available, a primary physician can best assist individuals to tailor treatments to effectively meet their needs (Ward, Klesges, & Halpern, 1997).

NIGHTMARES

Nightmares are defined as disturbing dreams associated with anxiety or fear that cause an awakening from sleep. Generally, the sufferer quickly becomes alert after awakening and readily recalls the details of the dream. Nightmares are a universal human experience and have engendered much literary attention but only limited empirical research. One aspect of dreams and nightmares that make them difficult to study is the fact that they cannot be directly observed. Dreams can only be recalled following awakening, and the fidelity of recall is not known. For example, it is possible that dream recall is limited to dream events occurring in the period immediately prior to arousal. Further, dream recall is subject to retrieval biases in which the subject will impose order on what can be chaotic mental experience.

Nightmares are associated with rapid eye movement (REM) sleep or light stages of Non-REM sleep. Nightmares typically occur in the last hours of sleep when the sufferer is more easily aroused. Studies that involve awakening subjects at various time points across the sleep period have found that the extent of dream recall increases as a function of time elapsed since sleep onset, irrespective of sleep stage (Rosenlicht, Maloney, & Feinberg, 1994). Thus, nightmares experienced at the end of the sleep period are associated with better recall than those occurring early in the sleep period.

Nightmares are often confused with night terrors, which represent a clinically distinct entity. Night terrors involve an incomplete awakening from deep non-rapid eye movement (NREM) sleep and are associated with disorientation, severe distress, and prominent autonomic arousal. During the night terror, the sufferer, most typically a young child, is difficult to awaken. Following complete awakening, the sufferer usually has absent or vague recall of dream mentation. Night terrors usually occur in the first hours of sleep when non-REM slow wave sleep stages are prominent.

While nightmares are experienced universally, the experience of frequent nightmares is considerably less common. The *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association [ApA], 1994) include the diagnosis of Nightmare Disorder, which was formerly referred to as Dream Anxiety Disorder. The criteria for this disorder include repeated awakenings from sleep with recall of frightening dreams that lead to significant impairment. Though the precise epidemiology of this disorder has yet to be characterized, the available data suggest that it occurs in 10 to 50 percent of children (ApA, 1994), with a peak incidence between the ages of 3 and 6 (Leung & Robson, 1993) and a decline in frequency with age (Hartmann, 1984). Nightmares occur with less frequency in adults and can be associated with alcohol withdrawal, dopamine stimulating medications, or withdrawal of REM-suppressing medication. Surveys have found that 10 to 29% of college students report having a nightmare once or more per month (Feldman & Hersen, 1967, Belicky & Belicky, 1982). A survey of 1006 adults, ages 18 to 80, in Los Angeles found that 5.3% of respondents reported that "frightening dreams" were a current problem (Bixler, et al. 1979). This survey as well as others (Coren, 1994) have reported a higher prevalence of frightening dreams in women. Unfortunately, little polysomnography data are available in adults with Nightmare Disorder, in part because nightmares are rarely captured in the sleep laboratory. Further, survey data are limited by the fact that subjects are often confused about the difference between night terrors and nightmares (Hartmann, 1984).

There has long been an interest in the relationship between trauma exposure and nightmares (Freud, 1920/1953; Kardiner & Spiegel, 1947; Horowitz, 1976; Brett & Ostroff, 1985; Ross, Ball, Sullivan, & Caroff, 1989). Subjectively, the experience of the nightmare feels as distressing as a traumatic experience during waking life. The nightmare is associated with the full sensory experience of an autonomic fear response. When nightmares occur during rapid eye movement sleep, a sleep stage in which skeletal muscles are atonic, the sufferer may experience a sense of paralysis and an inability to escape. Hartmann, in his studies of frequent nightmare sufferers, found that adult exposure to violent assault increased nightmare frequency, though he was not able to find a history of early childhood trauma (1984). Kales et al. (1980) also found that the onset of nightmares was preceded by "major life events." The National Comorbidity Survey reports a lifetime prevalence of Post-Traumatic Stress Disorder (PTSD) of 10.4% in women and 5.0% in men (Kessler Sonnega, Bronet, Hughes, & Nelson, 1995), which is similar to the gender ratio reported in frequent nightmare sufferers.

At present there are insufficient data to validate the diagnosis of Nightmare Disorder as a separate nosologic entity apart from PTSD. One large study of combat veterans found that frequent nightmares were virtually specific for those diagnosed with PTSD at the time of the survey (Neylan et al., 1998). In this study, combat exposure was highly associated with nightmares, moderately associated with sleep onset insomnia, and only weakly related to sleep maintenance insomnia. These relationships are consistent with the results of the combat veteran twin study (True et al., 1993), which showed that combat exposure was highly correlated with reports of dreams and nightmares and only weakly associated with sleep maintenance insomnia. These observations are also consistent with several other studies that show a low to moderate correlation between nightmares and other domains of sleep disturbance (Coren, 1994; Krakow, Tandberg, Scriggins, & Barey, 1995). Thus, the nightmare appears to be the primary domain of sleep disturbance related to exposure to traumatic stress.

There is no standardized treatment for frequent nightmares. There are a number of small scale open-label trials using sedating antidepressants, cyproheptadine, benzodiazepine, clonidine, guanfacine, and prazosin (Raskind et

al., 2002). None of these has been systematically studied in large randomized controlled trials. One novel treatment for repetitive nightmares is dream rehearsal therapy. Nightmare sufferers describe their nightmares in the context of group psychotherapy. They then repetitively rehearse an alternate and nontraumatic outcome to their nightmare narrative. This technique has been found to reduce the frequency and intensity of recurrent nightmares (Krakow et al., 2001).

NOISE EFFECTS

Noise is defined as unwanted sound. Its intensity is measured in decibels (dB). Zero dB is defined as the weakest noise that a person with normal hearing can just barely detect in quiet surroundings, 55 dB is equivalent to light traffic sounds, and 120 dB is equivalent to jet takeoff from 200 feet away. Most behavioral studies use a modified dB scale, called the *dBA scale,* devised to approximate perceived loudness. This scale assigns higher weights to high-frequency sounds, since they are perceived as louder than low-frequency sounds of equal sound pressure.

Noise pollution is a worrisome problem in the United States. The Environmental Protection Agency (EPA) has estimated that more than 70 million Americans live in neighborhoods noisy enough to be annoying and to interfere with communication and sleep. More than 50% of production workers are exposed to workplace noise loud enough to damage hearing.

Noise is by definition unwanted and therefore frustrating and tension-inducing. As a stressor, it alters the functioning of cardiovascular, endocrine, respiratory, and digestive systems, and is also suspected of having damaging effects on mental health.

The hearing loss effects of noise are well established. The EPA estimates that 1 out of every 10 Americans is exposed to noise levels of sufficient intensity and duration to create permanent hearing losses. Hearing losses do not

hurt and are not immediately apparent, but even minor hearing impairments seem to enhance susceptibility to further injury in the middle and late years.

The consequences of noise on performance cannot easily be predicted. They depend on the noise, the performance, the meaning of the sound, and the social context of the person performing. If people have clear warning of the need to react and receive easily visible cues, loud noise shows little or no overall effects on their work. In general, novel or unusual noises are more bothersome than familiar noise. However, familiar noises louder than 95 dBA—especially if unpredictable, uncontrollable, and intermittent—are disruptive. Typically, noise leads to variable performance—moments of inefficiency interspersed with normal and compensatory spurts of efficient performance. The lapses make workers more accident prone.

In academic settings, adverse effects have been documented repeatedly by well-controlled studies that take into account the socioeconomic and racial characteristics of the participants and use comparison groups. Among the effects of noisy homes and schools are impairment of auditory and visual discrimination, reading and visual-motor skills, overall scholastic achievement, and persistence in the face of frustration. One explanation for these effects is that noise disrupts the teaching-learning process, resulting eventually in cumulative deficits. Some investigators believe that the stressful effects of noise are ameliorated when people have accurate expectations about or (at least perceived) control over the noise.

Noise levels influence people's social conduct, as well. A number of experimental studies have found that individuals exposed to noise tend to be less helpful than those not exposed. Sheldon Cohen has suggested that noise causes subjects to focus their attention on salient aspects of the situation so they fail to notice interpersonal cues. Alternatively, decreases in helping might result from feelings of anger or frustration.

L. L. Davidoff

NONASSOCIATIVE LEARNING

From a biological viewpoint, learning is the process of acquiring new knowledge about the environment and the self necessary for survival of the species. Two major classes of learning can be distinguished: nonassociative and associative. In *nonassociative* learning, the subject learns about a stimulus by being repeatedly exposed to it. Three forms of nonassociative learning are distinguished: habituation, dishabituation, and sensitization. Habituation consists in a reduced response upon repeated presentation of the stimulus. For example, when a loud noise is repeatedly presented to a subject, the startle response rapidly habituates. Dishabituation is the recovery of habituation to a given stimulus upon presentation of a new salient stimulus. Sensitization is an increased response to a stimulus upon its repeated presentation. An example of sensitization is the increased response to a mild tactile stimulus after a painful pinch.

Habituation has been well studied in the defensive reflexes of marine mollusk Aplysia. In these studies habituation was found to be due to a decrease in synaptic transmission between sensory neurons and interneurons and motor neurons. With repeated stimulation, the synaptic potential generated by sensory neurons on interneurons and motor cells become progressively smaller because the amount of transmitter released into the synaptic cleft is decreased. After these modifications the reflex response is reduced. This reduction in the synaptic transmission can last for many minutes. Changes in the synaptic connections between several interneurons and motor neurons represent the components of the storage process for the short-term memory for habituation. This memory storage depends on plastic changes in the strength of preexisting connections. Habituation does not depend on specialized memory neurons that store information, but on neurons that are integral components of a normal reflex pathway. Different types of experiences may be stored in different cells that have many functions other than storing information. The duration of the habituation depends on the extent of training: a single training session of 10 stimuli in Aplysia produces a short-term habituation lasting few minutes, but four training sessions produce a long-term change lasting up to 3 weeks.

Habituation takes place also in the central nervous system of mammals. By monitoring in vivo the release of dopamine in different brain areas of rats using the microdialysis technique, it has been found that dopamine in the nucleus accumbens shell is also involved in the habituation phenomenon. Thus in rats, after a feeding of an unusual palatable food, such as Fonzies or chocolate, extracellular dopamine increases in the nucleus accumbens shell, but a second meal of the same food given after either 2 hours, 1 day, or 3 days fails to activate dopaminergic transmission. In addition, the delayed increase after an aversive gustatory stimulus (like quinine solutions) underwent habituation after a single trial. Recovery of responsiveness and of habituation takes place 5 days after the last exposure to the stimulus. In contrast, exposure to Fonzies or chocolate or quinine increases the extracellular dopamine in the prefrontal cortex, and a second exposure after 2 hours is able again to stimulate dopaminergic transmission. Therefore, in the prefrontal cortex, in contrast to the nucleus accumbens, dopamine does not undergo habituation.

Sensitization is a more complex form of nonassociative learning and it is well studied in the gill-withdrawal reflex in Aplysia. A single stimulus can produce a reflex enhancement that lasts minutes (short-term sensitization), and afterwards it can produce an enhancement that lasts days or

weeks (long-term sensitization). Short-term sensitization is produced following a single noxious stimulus to the head or tail. Synapses made by the sensory neurons on interneurons and motor neurons become modified. After sensitizing the stimulus, a group of facilitating interneurons that synapse on the sensory neurons, some of which are serotoninergic, become activated. There is an enhanced transmitter release from the sensory neurons because more transmitter than normal is available for release and there is a larger postsynaptic potential in the motor neurons. The consequence is an enhanced activation of interneurons and motor neurons, and thus an enhanced behavioral response (i.e., sensitization).

In long-term sensitization there are similar, but more extended, modifications than in the short-term process. In both short- and long-term sensitization there is an increase in synaptic strength due to the enhanced transmitter release, but long-term facilitation requires the synthesis of new protein and mRNA. Repeated training prolonged activation of protein kinasi A that phosphorylates nuclear regulatory proteins. These proteins affect the regulatory regions of DNA, increasing transcription of RNA and synthesis of specific proteins. One of the newly synthetized proteins restructuring of the axon arbor. With this process sensory neurons can form other connections with the same motor neurons or make new connections with other cells. In both short-term and long-term sensitization, the enhanced responses of the animal to test stimuli depend on enhanced release of the transmitter from sensory neurons to interneurons or to motor neurons at the level of preexisting synapses, but increases in axonal arborization and synaptic contacts are exclusive of long-term sensitization. The enhanced and prolonged activation of interneurons and cells depends on more synaptic connections with sensory neurons.

Studies about gustatory stimuli show that dopamine transmission is activated by unpredicted appetitive or aversive gustatory stimuli in a different manner in the two different compartments of the nucleus accumbens: the medioventral shell and the laterodorsal core. In fact, while dopamine transmission is activated by Fonzies and chocolate feeding, and in a delayed manner by quinine solutions, to a larger extent in the shell than in the core, preexposure to gustatory stimulus inhibits the dopamine response in the shell but potentiates it in the core. The response properties of dopamine transmission in the nucleus accumbens core, while different from those of the nucleus accumbens shell, are similar to those of the prefrontal cortex.

The responsiveness of dopamine transmission to gustatory stimuli in the nucleus accumbens compartments seems to differ in its adaptive properties. While the dopaminergic responsiveness to gustatory stimulus in the nucleus accumbens core is sensitized by preexposure to it, in the shell it is inhibited. Dopamine physically released in the nucleus accumbens shell by gustatory stimulus might enable the association between the stimulus properties and the biological consequences of feeding. By this mechanism, gustatory stimuli are attributed a motivational valence which determines the specific consummatory response to be emitted by the subject upon further encounter of the same food. The potentiation of dopaminergic transmission in the nucleus accumbens core by preexposure to gustatory stimulus is consistent with an activational role of dopamine in the nucleus accumbens, and with the possibility that the release of dopamine in the nucleus accumbens core facilitates the motor expression of motivated behavior.

NONPARAMETRIC STATISTICAL TESTS

Nonparametric statistical methods are based on weaker assumptions than standard parametric procedures such as the *t*-test, analysis of variance, and inferential procedures

associated with the Pearson correlation coefficient. For example, the usual *t*-test for two independent groups assumes that the scores in the groups are independent and are randomly sampled from normally distributed populations with equal variances. In contrast, nonparametric or distribution-free tests do not make such strong assumptions about the populations.

Although there is agreement that many standard parametric tests are fairly robust with regard to type 1 error when the assumption of normality is violated, the power of these tests may be severely reduced when the populations are not normally distributed. In particular, severe losses of power may occur when the underlying populations are *heavy tailed;* that is, when there are more scores in the extremes of the distributions (outliers) than would be expected for a normal distribution. In certain cases, it may be shown that particular nonparametric tests have considerably more power than the corresponding parametric tests. However, nonparametric tests are not completely free of assumptions, and unless certain conditions are met, do not test the same null hypotheses as the corresponding parametric tests. For example, the Wilcoxon–Mann–Whitney test based on ranks is a commonly used "nonparametric" analog of the independent-groups *t*-test. The null hypothesis of the *t*-test is that the population means of the two groups are equal. If one does not wish to make assumptions about the underlying populations, yet wants to make inferences about measures of location such as the mean or median, one must make the assumption (the so-called "shift" assumption) that, whatever their characteristics, the populations are identical except for their locations. Only in this case do the *t*- and Wilcoxon–Mann–Whitney tests both address the same null hypothesis.

Rationales For Some Classes of Nonparametric Tests and Some Examples

In most nonparametric tests, the original scores or observations are replaced by other variables that contain less information, so that the statistical tests that are used are less influenced by extreme scores. An important class of tests uses the ordinal properties of the data. The original observations are first replaced by the ranks from 1 to N, and subsequent operations are performed only on the ranks. Some of these procedures (but certainly not all) are computationally simple because the means and variances of the first N integers are easily obtained. It has been shown that some of these procedures are equivalent to what would be obtained by first converting the scores to ranks, then performing the standard parametric tests on these ranks.

If equality of population distributions except for location can be assumed, both the Wilcoxon–Mann–Whitney procedure mentioned above and the Kruskal–Wallis procedure, the generalization to more than two conditions, test hypotheses about location with more power than their parametric analogues when the underlying distributions are heavy tailed. If identical distributions cannot be assumed but homogeneity of the variances *of the ranks* can be assumed, Vargha and Delaney (1998) have shown that what is tested is whether there is a general tendency for scores in at least one of the populations to be larger (or smaller) than those in all of the remaining populations, taken together. If this holistic hypothesis is of interest in situations in which homogeneity of variance or ranks cannot be assumed, alternatives to the *t*-test and ANOVA procedure (such as the Welch test) performed on the ranks are recommended.

Another important class of tests employs information only about whether an observation is above or below some value, such as the median. All values above the median might be assigned a "plus" and those below it a "minus," so that, in effect, they are replaced by a new variable that can take on only two values.

A number of nonparametric analogs exist for repeated-measures ANOVAs and matched-group *t*-tests. One approach is simply to rank all of the scores, then perform a repeated-measures ANOVA on the ranks. This test is less powerful than the corresponding ANOVA performed on the original scores if the underlying populations have normal distributions. However, when the distributions are heavy tailed, the ANOVA on the ranks can be more powerful. This approach is recommended when samples come from populations that are heavy tailed and symmetric. If the distributions are skewed and the average correlation is not close to zero, the Friedman chi-square test, which involves ranking the scores separately for each subject, will tend to be more powerful.

A very different approach does not depend on the idea of the usual population model of inference, in which inferences are made about parent populations from which the available data have been randomly sampled. Rather, the way in which a sample of scores, however acquired, is distributed across two or more treatment conditions is considered by *permutation tests.* If the scores are distributed in ways that would be unusual had they simply been randomly assigned to conditions, a treatment effect is indicated.

NONVERBAL COMMUNICATION

Nonverbal communication is the nonlinguistic transmission of information through visual, auditory, tactile, and kinesthetic channels. Like other forms of communication, nonverbal communication involves encoding and decoding processes. Encoding is the act of generating the information and decoding is the act of interpreting the information. Nonverbal encoding processes include facial expressions, gestures, posture, tone of voice, tactile stimulation such as touch, and body movements like moving closer to or farther away from a person or object. Decoding processes involve the use of received sensations combined with previous experience in interpreting and understanding the information. Although nonverbal communication may refer to mass communication such as television, art products, and multimedia productions, in this discussion the emphasis is on interpersonal communication, whether face-to-face or by telephone.

Culture has a significant impact on nonverbal communication. For instance, the ways people use gestures are specific from culture to culture. People in the western world nod their heads to signal agreement, but people in South Asian countries often move their heads from side to side to convey a similar meaning. While westerners interpret the O sign using the finger and thumb as OK, the parking man in Indonesia would use the sign as an order to the driver to put the car's gear shift in a zero position. This misunderstanding will create a problem when the parking man has to push the car for a parking space. Most Asians use gestures like bowing to show their respect to other people. Many Asians are silent when they are disappointed and continue using their usual tone of voice and smiling face even though they are in that emotional state. Most Americans seem more comfortable than Asians in using nonverbal communication to encode their emotional states.

Scientists and practitioners have long been aware of the importance of the relationship between nonverbal communication and emotion. In 1872, Charles Darwin published *The Expression of the Emotions in Man and Animals.* In 1905, Sigmund Freud observed that even though someone does not say anything, parts of the body will move and convey to the observer that something is happening inside. By the 1970s and 1980s, researchers had started to develop refined procedures and technology for measuring the encoding and decoding processes of nonverbal communication. The methods vary from social to physiological and from descriptive to experimental studies. They have generated general laws and measures of individual differences in the transmission of cognitive and affective information.

Paul Ekman has studied extensively facial expression and emotion. He began studying this topic in 1965 by asking a single question: Are facial expression and emotion universal or culture specific? He could not find a simple answer, and that led him to more questions. With Friesen, Ekman originated the Facial Action Coding System (FACS) in 1978. FACS is a reliable rating technique using photographs or a video for encoding and decoding basic emotions such as anger, disgust, fear, happiness, sadness, and surprise. David Matsumoto has also developed an instrument to compare Japanese and American facial expressions.

Another nonverbal cue that helps individuals detect emotions experienced by another person is voice. Using vocal cues, sometimes called paralinguistics or prosody, in 1966 Norman Sundberg developed a Test of Implied Meanings (TIM) using judgments of the "real meanings" of sentences spoken by actors. This test showed differences favoring skilled therapists over others, as well as sex differences favoring females. The most developed and researched paralinguistic test is the Profile of Nonverbal Sensitivity (PONS), developed by Rosenthal, Hall, DiMatteo, and Archer in 1979. The PONS includes visual and auditory stimuli. One of its findings is that facial expression is superior in decoding accuracy as compared to other channels.

Intimacy can be detected from proxemics, or the use of space in gestures, postures, and touching. Patterson reported in 1990 that the more intimate a relationship between individuals, the more nonverbal communication is observed. Proxemics between the two are closer; they do more hugging and touching, although the amount and manner of physical contact is related to culture. In 1990, Hall and Veccia studied touching between the sexes. They found that both men and women touched each other on purpose with the same frequency. The difference was that males tended to put their arms on the females' shoulders, but females put their arms on the males' arms (perhaps related to differences in height).

The expression and perception of mental states is a complex phenomenon that constantly presents challenges in interpersonal communication. How sincere and truthful is a person? How intensely does a companion feel? Is facial expression of emotion universal or culture specific? How do people use gestures, tone of voice, and other nonverbal cues to perceive emotional states in others? Will touch affect others in a positive or negative way? If it is positive, is touch useful for the healing process? Is a measure of nonverbal behavior as an indicator of hospital patients' mental state useful to improve health providers' services? Will increasing contact in a global society require and lead to greater ability to encode and decode mental states in others? How important is nonverbal communication in the negotiation process among politicians and decision makers, and can a

better understanding of the mental states of others enhance peace in the global world? These are only a few of many important questions for future research. The advancement of theory and research in nonverbal communication is crucial for improving the understanding of basic processes in human interaction.

NOREPINEPHRINE

Norepinephrine is the main neurotransmitter released from noradrenergic (sympathetic) nerve terminals. The noradrenergic neurons occur in both the central and the peripheral autonomic nervous systems. Central noradrenergic fibers arise in neurons located in the brain stem, mainly in the ventrolateral and the dorsomedial medulla oblongata, the locus ceruleus, and the subceruleus area. In the peripheral autonomic nervous system, noradrenergic neurons are located in the para- and prevertebral sympathetic ganglia from which postganglionic fibers originate and supply various organs and blood vessels.

Chemically, norepinephrine is a catecholamine; "catechol" refers to compounds containing an aromatic benzene ring with two adjacent hydroxyl groups (Kopin, 1985; Pacak, Palkovits, Kopin, & Goldstein, 1995). Catechol itself (1,2 dihydroxybenzene) does not occur as an endogenous compound in animals. Endogenous catechols include the catecholamine precursor, dihydroxyphenylalanine, its amine products (dopamine, norepinephrine, and epinephrine), and their deaminated metabolites.

The first and rate-limiting enzymatic step in norepinephrine biosynthesis is hydroxylation of tyrosine to form dihydroxyphenylalanine (Figure 1). This reaction is catalyzed by tyrosine hydroxylase and requires tetrahydrobiopterin as a cofactor. Free dopamine and norepinephrine in the cytoplasm of dopaminergic and noradrenergic neurons inhibit tyrosine hydroxylase and thereby regulate their own synthesis. Hydroxylation of tyrosine is followed by decarboxylation of dihydroxyphenylalanine by L-aromatic amino acid decarboxylase, and this reaction occurs in the cytoplasm of neuronal and nonneuronal cells to yield dopamine (Kagedal & Goldstein, 1988; Kopin, 1985; Pacak et al., 1995).

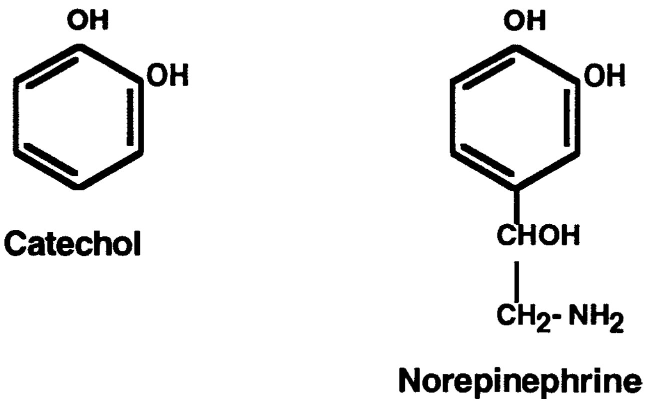

Figure 1. Chemical structure of catechol and norepinephrine.

Dopamine is transported via a nonspecific amine transporter into vesicles found in noradrenergic terminals. In the vesicles hydroxylation of dopamine occurs by dopamine-β-hydroxylase to yield norepinephrine (Kagedal & Goldstein, 1988). In the brain and some peripheral tissues, especially adrenal medulla, norepinephrine is converted to epinephrine by phenylethanolamine-N-methyltransferase.

Upon nerve stimulation, a soluble vesicular content including norepinephrine and other cotransmitters such as chromogranins, neuropeptide Y, dopamine-b-hydroxylase, adenosine triphosphate, and enkephalins are released during noradrenergic nerve terminal depolarization. Sodium and calcium entering nerve terminals during depolarization are thought to evoke exocytosis. In contrast, chloride ions may exert an inhibitory presynaptic effect.

Table 1. Effects of Some Drugs on Noradrenergic Neurotransmission

Drug	Inhibitory effect	Stimulatory effect
Acetylcholine (nicotine receptor)	—	NE release
Acetylcholine	NE release	—
ACTH	—	NE release
Adenosine	NE release	—
Angiotensin II	—	NE release
Clorgyline	Monoamine oxidase-A	—
Cocaine	Uptake–1	—
Desimipramine	Uptake–1	—
Epinephrine (presynaptic β_2-adrenoreceptors)	—	NE release
GABA ($GABA_A$ receptor)	—	NE release
GABA	NE release	—
Glucocorticoids	Uptake–2	—
Lithium	Uptake–1	—
Opioids	NE release	—
Ouabain	Uptake–1	Na^+-mediated efflux
Pargyline	Monoamine oxidase-B	—
Phenoxybenzamine	Uptake–1	—
Prostaglandins E	NE release	—
Reserpine	Vesicular uptake	—
Tricyclic antidepressants	Uptake–1	—
Tyramine	—	Vesicular release
α-Methyldopa	Dopa decarboxylase	—

Notes: ACTH: adrenocorticotropin; NE: norepinephrine; GABA: gamma-amino butyric acid.

The metabolic disposition of norepinephrine differs in neurons and in nonneuronal cells (Figure 2). Neurons contain monoamine oxidase (a mitochondrial enzyme) but little if any catechol-O-methyl transferase. Axoplasmic norepinephrine is metabolized mainly by deamination in neurons, whereas nonneuronal cells contain catechol-O-methyl transferase as well as monoamine oxidase (Kopin, 1985). The product of norepinephrine deamination, 3,4 dihydroxyphenylglycolaldehyde, is reduced to form 3,4 dihydroxyphenylglycol. Most (60%–80%) of the dihydroxyphenylglycol formed in sympathetic nerve terminals is derived from vesicular norepinephrine. In subjects at rest, plasma dihydroxyphenylglycol levels are determined mainly by vesicular turnover, rather than by reuptake of released norepinephrine. Dihydroxyphenylglycol diffuses freely and rapidly across cell membranes and reaches extraneuronal cells, extracellular fluid, and plasma.

Norepinephrine released from peripheral nerve terminals is removed extensively by reuptake (90%, Uptake-1) and to a lesser degree by extraneuronal uptake (Uptake-2; Kopin, 1985; Pacak et al., 1995). In the brain, the relative roles of these modes of inactivation are poorly understood. Norepinephrine that enters the neurons is largely taken up into vesicles (Table 1). A portion of this norepinephrine (the exact amount of the portion is unknown in brain noradrenergic terminals) is thought to leak out of the vesicles and undergo metabolism in the axoplasm.

Norepinephrine and dihydroxyphenylglycol that enter extraneuronal cells, which, as indicated above, contain catechol-O-methyltransferase as well as monoamine oxidase, are O-methylated to form normetanephrine and further metabolized to methoxyhydroxyphenylglycol. Methoxyhydroxyphenylglycol is also formed from dihydroxyphenylglycol. Plasma normetanephrine accounts for a relatively small proportion (less than 10%) of the total norepinephrine metabolized in the body and is derived mainly from norepinephrine metabolized before entry into plasma and the remainder (45%) from norepinephrine after it enters plasma (Eisenhofer et al., 1995). The extent of nonneuronal metabolism of norepinephrine in the brain is poorly understood. Metoxyhydroxyphenylglycol in plasma is derived mainly either from dihydroxyphenylglycol formed in tissues or from normetanephrine formed in extraneuronal tissues before its entry into plasma. Thus, simultaneous measurements of norepinephrine and its metabolites provide a comprehensive picture of norepinephrine synthesis, turnover, and metabolism in brain and peripheral tissues.

In contrast to sympathetic nerve terminals where norepinephrine is released into the synaptic cleft and acts locally (only a small portion of norepinephrine can reach the

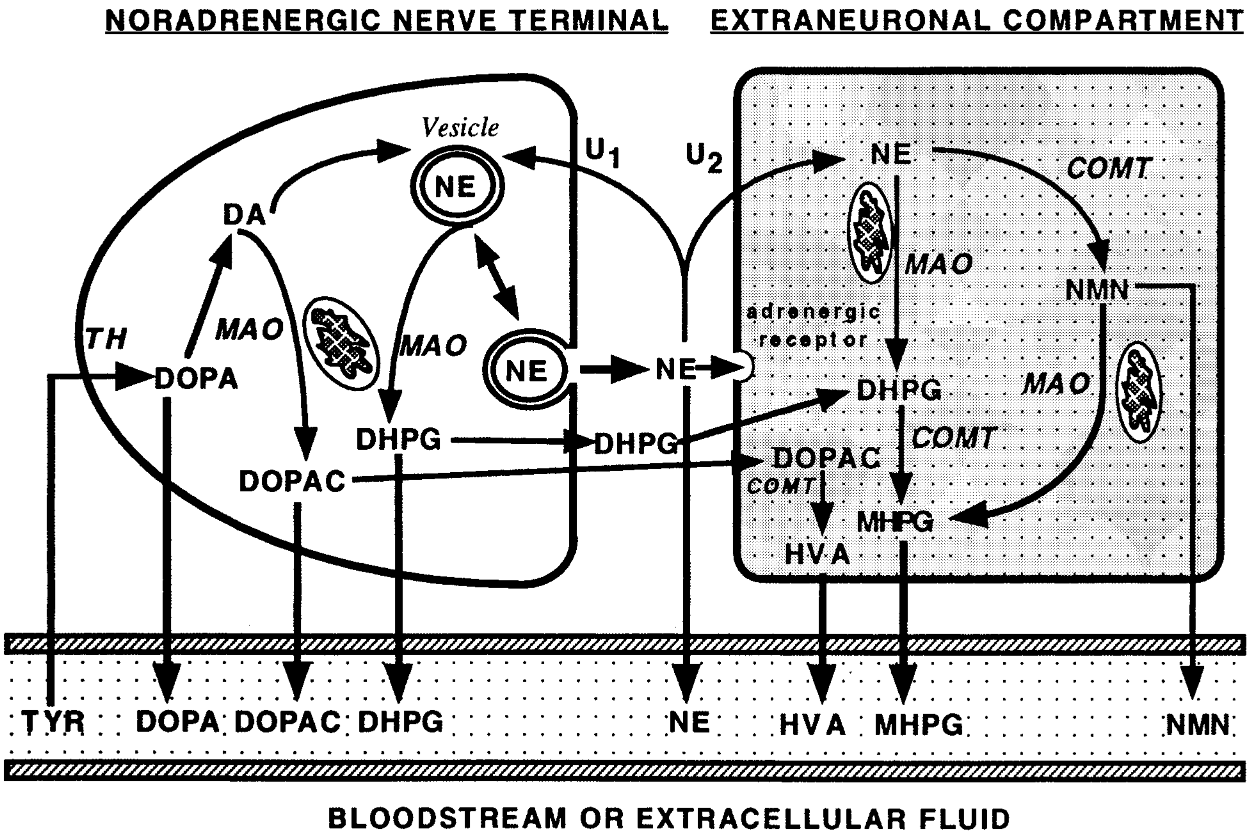

Figure 2. Diagram showing the synthesis, release, uptake, and metabolism of norepinephrine (NE).
Abbreviations: COMT: catechol-*O*-methyltransferase; DA: dopamine; DHPG: dihydroxyphenylglycol; DOPA: dihydroxyphenylalanine; DOPAC: dihydroxyphenylacetic acid; HVA: homovanillic acid; MAO: monoamine hydroxylase; NMN: normetanephrine; TH: tyrosine hybroxylase.

bloodstream) via alpha and beta adrenergic receptors, epinephrine and norepinephrine (approximately 20% of the total body amount) released from the adrenal medulla are secreted directly into the adrenal vein and in a very short time reach all sites in the body except for most brain regions (catecholamines do not cross the blood-brain barrier).

Norepinephrine released from noradrenergic terminals exerts its effect via adrenoceptors (e.g., α_1: blood vessel constriction, uterus, sphincters of gastrointestinal tract and urinary bladder contractions; α_2: feedback inhibition of norepinephrine release; β_1: heart rate increase; β_2: relaxation of blood vessels, bronchi, sphincters of gastrointestinal tract and urinary bladder dilation).

Distinct patterns of sympathoneuronal activation during exposure to different situations have been demonstrated. Orthostasis, hyperthermia, and cold exposure evoke selective norepinephrine release, whereas hypoglycemia evokes large epinephrine responses.

The availability of simultaneous measurements of norepinephrine and its metabolites introduced a novel application of clinical catecholamine neurochemistry: the delineation of neurochemical patterns associated with specific genetic abnormalities (Goldstein et al., 1996). Such abnormalities are seen in phenylketonuria (abnormal phenylalanine and tyrosine hydroxylation), Menkes disease and some forms of orthostatic hypotension (dopamine-β-hydroxylase deficiency or decreased activity), Norrie's disease and aggressive behavior (monoamine oxidase deficiency), and velocardio-facil syndrome and DiGeorge syndrome (decreased catechol-O-methyl transferase activity).

NYMPHOMANIA

Broadly speaking, nymphomania refers to the condition of a woman whose sexual desire and/or behavior is referred to by terms like "insatiable," "abnormally intense," "unquenchable," "unrestrained," or "uncontrollable." In practice, the term is poorly defined and often loosely applied. It is usually distinguished from *sexual promiscuity,* but many proposed definitions use the two expressions interchangeably.

A woman who has many sexual encounters, whose lovers are culturally considered to be inappropriate, who is anorgasmic despite frequent sexual contacts, and whose sexual behaviors rarely take place within the context of an intense emotional relationship fits the classical and folkloric stereotype. Furthermore, Levitt points out that the various conceptions of nymphomania neglect the potentially important factor of opportunity as reflected in physical attractiveness, place of residence, type of occupation, and marital status.

Albert Ellis and Edward Sagarin distinguish between *controlled promiscuity* and *endogenous nymphomania.* The former refers to the not-too-unusual, multipartnered existence of a woman who is completely functional, while the latter is "seldom found outside the disturbed wards of mental hospitals." Ellis adds that he has not encountered a single endogenous nymphomaniac in his extensive clinical practice.

O

OBSERVATIONAL METHODS

Observations, whether formal or informal, consist of taking note of events or occurrences and making a record of what is observed. Observation is basic to all science, and special methods have been devised to make observations of behavior objective and reliable.

In *controlled observation,* a situation is prearranged or contrived to study the responses of people or animals to certain stimulus conditions. Because controlled observation involves special procedures, *uncontrolled observation,* in which the observer exerts no control over the situation and merely takes note of behavior in situ, is more common.

Much of what is known about the dynamics of personality and mental disorder is the result of observations made by people in clinical settings. The *clinical method* is not completely objective; not only does the therapist–observer affect the patient's behavior, but the patient also affects the reactions of the therapist.

In scientific research it is usually considered advisable for the observers to remain as unobtrusive as possible, not interacting in any way with those being observed. However, if the researcher elects to become a part of the observational situation and be a *participant observer,* the effects of the observer's presence on the behavior of the performers need to be considered in interpreting the research findings.

An important first step in improving the accuracy of observations is to train the observers. Observers must be made aware of the effects of their own biases, conduct, and condition on what is being observed, and of the tendency to confuse fact with interpretation. Furthermore, the influence of the situational context in which observations are made should be taken into account in interpreting the findings.

Obtaining meaningful results from an observational study also demands that the sample of observed behavior be representative, which is usually time-consuming and expensive. To reduce the time, expense, and volume of data obtained from continuous observations of behavior, special data-sampling procedures are employed. In *incident sampling,* only specified behavioral incidents are noted and recorded. A second procedure, *time sampling,* involves making a series of observations, each lasting only a few minutes, over a period of a day or so. Finally, the use of an *observational schedule,* such as a rating scale or checklist filled out during or shortly after the behavioral occurrence, can improve the reliability of observations.

Observations are also made in developmental research, surveys, correlational studies, and even experiments. For example, periodic observations of the development of the same age group of individuals over a period of months or years (*longitudinal investigation*), or of different age groups of people at a specific point in time (*cross-sectional investigation*), are common in developmental research. Content analysis of self-observations recorded in diaries, autobiographies, letters, and other personal documents also provide insight into personality dynamics.

OBSESSIONS

Obsessions are described in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 1994) as recurrent intrusive thoughts, impulses, or images that produce anxiety or discomfort. Individuals with Obsessive-Compulsive Disorder (OCD) usually try to suppress or neutralize obsessions with other thoughts or actions. Typical themes for obsessions are harming, sexuality, contamination, concerns with disease, religion, superstition, or otherwise neutral thoughts ("What if I cannot stop thinking about my breathing?"). Normally the individuals with OCD know that the obsessions originate in their own mind and are not coming from the outside.

Although pure obsessions (i.e., obsessions without overt compulsions) have traditionally been assumed to be infrequent, treatment centers worldwide have reported between 1.5% and 44% of OCD patients who report no overt compulsions (median = 20%; for a review see Freeston & Ladouceur, 1997). Moreover, epidemiologic studies have found that in the community, the percentage of individuals with OCD suffering from pure obsessions may be as high as 60%.

Several theories have attempted to explain the development of obsessional problems and related compulsions. For example, Mowrer (1960) described a two-stage theory, stating that a fear of specific stimuli is first learned through classical conditioning (stage 1, e.g., the patient feels anx-

ious after thinking a blasphemous thought) and then maintained by operant conditioning (stage 2) as the individual learns to engage in ritualistic behavior to decrease anxiety (e.g., the patient prays compulsively). Thus, rituals are preserved by reinforcing properties of anxiety reduction. Because reinforced behaviors will occur more often in the future, the frequency of rituals increases. Rituals or avoidance behavior maintain the fear response because the sufferer does not stay in contact with the stimulus long enough for the anxiety to extinguish.

More recent theories for the development of obsessional problems have suggested information processing biases and deficits with respect to decision making, failures of inhibition, and memory (for a detailed review see Steketee, Frost, Rheaume, & Wilhelm, 1998). For example, Enright and Beech (1993) showed that OCD patients had difficulty inhibiting the processing of irrelevant, emotionally neutral material. This difficulty may account for the frequency of intrusive thoughts in OCD. The evidence for memory deficits underlying obsessional problems is inconclusive: several studies failed to find deficits but did find a lack of confidence in the sufferers' recall of their own actions (e.g., McNally & Kohlbeck, 1993).

Current cognitive models of OCD characterize intrusive thoughts as normal events that most people experience, indistinguishable from obsessional thoughts with respect to their content. Rachman and DeSilva (1978) found that those intrusive thoughts were reported by almost 90% of a nonclinical sample. Intrusive thoughts develop into obsessions not because of their content but because of the meaning individuals attribute to them. Nonobsessional individuals disregard intrusions and do not evaluate them as important, whereas people with OCD attend to them believing that they are meaningful. The appraisal of the intrusion may depend on underlying beliefs or assumptions acquired in a religious, cultural, or family context. People who appraise the intrusions in a maladaptive way experience negative emotions (e.g., guilt, anxiety) and fear negative consequences. Thus, in seeking ways to reduce discomfort they often engage in neutralizing strategies such as overt compulsions, mental rituals, avoidance behaviors, and attempts to suppress thoughts. However, a series of thought suppression experiments suggested that efforts to suppress specific thoughts resulted in an increase rather than a decrease of those thoughts (Wegner, 1989).

Faulty interpretations of intrusive thoughts have been categorized in several domains (Obsessive Compulsive Cognitions Working Group, 1997) and include overimportance of thoughts, the need to control thoughts, overestimation of threat, intolerance of uncertainty, perfectionism, and excessive responsibility.

Many OCD sufferers attach too much importance to the content and presence of their thoughts, and erroneously believe that other people do not have intrusive thoughts. They may believe that simply because a thought occurs, it is meaningful or indicates that they will act on it. Extreme beliefs about the importance and meaning of thoughts can lead to beliefs about having to exert control over them. For example, if an individual interprets an intrusive thought as indicating "I am evil," it is likely that this interpretation is followed by emotional discomfort and by attempts to remove the intrusion. Like other anxiety disorder sufferers, OCD patients often overestimate both the probability and the severity of negative outcomes; therefore, they may interpret situations as dangerous until proven safe, whereas most people consider a situation safe unless there is an indication of threat. The need for certainty in OCD patients or intolerance of uncertainty is another frequently noted feature of OCD. The tendency of OCD patients to overestimate danger may be related to their difficulties with ambiguous situations and with making decisions. Theories of OCD have linked intolerance of ambiguous situations to perfectionism. For example, OCD patients may feel uncertain about the efficacy of their efforts to minimize harm when a perfect solution cannot be determined. The domain of excessive responsibility has received the most attention in recent studies and refers to the assumption that one has the pivotal power to generate or avert unwanted outcomes (e.g., Salkovskis, 1985). Excessive responsibility can induce guilt which is then reduced by compulsions. Recent studies have tested cognitive treatments that address those cognitive domains (see Steketee et al., 1998).

In summary, several theories have been introduced for the development of obsessional problems. Behavioral, biological, and other theories examining the cognitive aspects of the development of obsessional problems have been proposed. Current cognitive research suggests that obsessional problems are the result of maladaptive interpretations of intrusive thoughts. A better understanding of obsessional problems may result from an integration of these different areas of research.

OBSESSIVE-COMPULSIVE DISORDER

Definition

Obsessive-Compulsive Disorder (OCD) is an anxiety disorder that involves two primary symptoms: obsessions and compulsions. *Obsessions* are thoughts, ideas, images, or doubts that are experienced as senseless, unwanted, and distressing. Although the person recognizes the thoughts as irrational, they often evoke anxiety about dreaded consequences. Common themes of obsessions include contamination; terrible mistakes; violent, sexual, or blasphemous thoughts; or thoughts about things not being "just right." *Compulsions* are urges to perform purposeful behavioral or mental rituals that serve to neutralize the anxiety and doubt evoked by obsessional thoughts. Examples include handwashing, checking, asking for reassurance, ordering/arranging, repeating routine activities, counting, and mentally praying or thinking a "good" thought.

Obsessions and compulsions are phenomenologically related. For example, a person with obsessional thoughts concerning contamination from "floor germs" may spend hours washing their hands or other objects thought to be contaminated. Someone with unwanted blasphemous thoughts might repeat prayers until the thought has disappeared. Similarly, a person with fears of causing a house fire may check that appliances are unplugged. Compulsive rituals sometimes take the form of mental acts such as repeating phrases to neutralize "bad" thoughts, attempting to suppress a thought, or mentally reviewing to gain reassurance that a mistake was not made.

Prevalence and Course

The prevalence of OCD is about 2 to 3% in the adult population and 1 to 2% in children. Although it may begin as early as the preschool years, the average age of onset is in the late teens to early twenties. Males tend to develop OCD at a younger age than females. Although the severity of obsessions and compulsions may wax and wane depending on the amount of general life stress, OCD is a persistent condition with a low rate of spontaneous remission. Without effective treatment, a chronic and deteriorating course can be expected.

Etiological Theories

The causes of OCD are largely unknown, yet its development most likely involves a biological vulnerability to anxiety in combination with psychosocial factors. There is no evidence to support psychoanalytic theories of OCD which propose that the interplay of unresolved childhood conflicts contribute to the development of obsessions and compulsions. The current leading theories of OCD include biological, behavioral, and cognitive behavioral explanations.

Biological

Biological models of OCD propose that the underlying pathophysiology of this disorder is abnormal serotonin functioning. In particular, individuals with OCD are thought to have a hypersensitivity in postsynaptic serotonin receptors. Indeed, studies have found evidence for elevated serotonin levels among OCD patients. Moreover, serotonin reuptake inhibitor (SRI) medication is more effective than other forms of pharmacotherapy in the treatment of OCD. It is important to note, however, that whereas some study results support the *serotonin hypothesis* of OCD, others do not support this model. Moreover, a specific mechanism by which serotonin function may be related to OCD symptoms has not been proposed.

Behavioral

Classical behavioral theories posit a two-stage process by which OCD develops and is maintained. In the first stage (fear acquisition), a natural event becomes associated with fear by being immediately paired with an aversive stimulus that evokes anxiety. For example, a knife may acquire the ability to elicit anxiety by being paired with a traumatic experience. In the second stage (maintenance), avoidance and compulsive rituals are negatively reinforced because they result in a reduction in anxiety. For example, if checking that the drawers are locked relieves distress evoked by thoughts of knives, this kind of checking is likely to be repeated whenever thoughts of knives occur. Although there is evidence that obsessional thoughts increase anxiety, and compulsive rituals reduce it, the classical behavioral model of OCD does not adequately explain the development of OCD symptoms.

Cognitive–Behavioral

The inadequacy of classical behavioral theories of OCD led to the development of cognitive–behavioral theories that

consider how patients interpret normally occurring intrusive thoughts. This model recognizes that most people have senseless thoughts now and then (e.g., *what if I stabbed someone I care about?*). However, OCD develops if one habitually appraises such thoughts in biased ways that lead to feeling overly responsible and threatened (e.g., *I'm an immoral person for thinking this,* or *my thoughts are equivalent to actions*). The result is preoccupation with the thought (obsessions) and increasingly anxious mood.

The fear and exaggerated sense of responsibility evoked by obsessional thoughts motivates the person with OCD to engage in compulsive rituals to reduce the probability of feared catastrophes. Rituals and avoidance are, however, excessive responses to stimuli and thoughts that are not actually threatening. According to this theory, such responses maintain obsessional anxiety because they (1) result in a short-term reduction in obsessional anxiety, and (2) prevent the person from realizing that their fears were unrealistic in the first place.

Treatment

Two treatments are effective for OCD: SRI pharmacotherapy and cognitive-behavioral therapy (CBT).

Pharmacotherapy

SRIs (clomipramine, fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram) are the most effective pharmacological treatment for OCD. These medications block the reuptake of serotonin, which is suspected to be related to OCD symptoms. On average, rates of improvement with adequate trials of SRIs (at least 12 weeks) range from 20% to 40%. However, response varies widely from patient to patient and side effects such as nausea, sleep disturbances, or decreased sex drive are common. Importantly, once pharmacotherapy is stopped OCD symptoms return in 85% of patients.

Cognitive–Behavioral Therapy

CBT is based on the behavioral and cognitive-behavioral models of OCD and is the most effective short- and long-term treatment for this disorder. Patients treated with CBT often achieve up to 65% reduction in their OCD symptoms. The two main CBT procedures are (1) exposure with response prevention (EX/RP) and (2) cognitive therapy. Exposure involves prolonged and repeated confrontation with situations that evoke obsessional fears, while response prevention entails refraining from carrying out compulsive rituals. EX/RP is thought to work by demonstrating that obsessional fears are unrealistic and that rituals are unnecessary to prevent feared catastrophes. Cognitive therapy involves using rational discourse to help patients recognize and correct faulty appraisals of intrusive thoughts. It is often used in conjunction with EX/RP.

OCCUPATIONAL INTERESTS

Because of the extensive concern of career development and career counselors with systematic measurement of career interests and adjustment, a general assessment of interests has become of major importance in the field. Among the issues involved have been the adequacy of psychometric approaches to measuring career interests; problems associated with sexism and/or racism in measuring career interests, particularly as these affect the language of the instruments; assumptions underlying the development of the interests; and the norms upon which the scores are based.

Interests are usually operationally defined by the instrument used to measure them, such as the Strong–Campbell Interest Inventory or the Kuder Occupational Interest Survey. Four generic types of interests are usually assumed to exist. *Manifest interests* are represented by the activities in which an individual actually engages; *expressed interests* are those identified by an individual when asked about his or her interests; *inventoried interests* are those measured by various instruments, such as the Strong–Campbell or the Kuder survey; and *tested interests* are inferred on the basis of the knowledge possessed by an individual about various fields of endeavor, on the assumption that the knowledge reflects involvement in pertinent activities.

It is generally agreed that among adolescents occupational interests as measured by inventories predict about as well as do expressed interests, and that adolescents' interests change over time. One reason interests do not predict occupational entry and satisfaction in adolescents well is that such variables as aptitudes, performance, and opportunity intervene significantly to determine occupational entry and achievement.

Most interest inventories are based on the general assumption that individuals who enter and find the same occupation satisfying share numerous characteristics, so the interest inventories strive to measure relevant personal characteristics. Currently, little is known about how interests actually develop, though various theoretical explanations stemming from social learning theory, psychoanalytic theory, and personality theory have been proposed to guide thought and research exploring interest development.

Psychometric Adequacy

Most measures of career interest have followed highly successful examples used by the two leaders in the field—the Strong–Campbell Interest Inventory and the Kuder Occupational Interest Survey. Over the years, these two instruments have increasingly been adapted to incorporate those characteristics of the other instruments that they previously lacked. The Strong–Campbell Interest Inventory in its original version primarily measured individuals' preferences for activities, occupations, and so on, and compared these to the preferences of satisfied employed members of particular occupations. The rationale was entirely empirical and no attempt was made in the development of this instrument to establish any other rationale underlying the score. On the other hand, the original Kuder measures were designed to assess different orientations toward the world that could be translated into interests. Individuals were assumed to possess inclinations toward certain kinds of activities, and these inclinations were assumed to be more related to certain occupations and less related to others. Over the years, many counselors used both instruments together because one provided information about the person and the other provided information about the world of work as it related to the person; as a result, the two instruments complemented each other.

Recognizing that each instrument had its limitations, their developers modified them over the years. The Kuder now includes empirically derived scores as well as the more theoretically derived ones, and the Strong–Campbell also now includes theoretically derived scores based on the Holland type of theory (Holland, 1966) as well as the traditional empirical scales. Potential users may have their own preferences for the psychometric underpinnings of one or the other instrument, but theoretically they measure the same sets of attributes.

These two instruments have dominated the field of interest measurement for more than half a century; other instruments have been developed and can be evaluated through the use of Buros's *Mental Measurements Yearbook,* but none have anywhere near the influence on measuring career interests that these two have had.

Other measures, such as the *Self-Directed Search* (SDS) of J. L. Holland (1979), have also been used widely. The SDS assesses interests differently from the Strong–Campbell or the Kuder Occupational Scales, and theoretical components of the SDS have been incorporated into the Strong–Campbell Interest Inventory. The SDS requires individuals to describe their career-related interests, activities, and competencies in terms of environments to which they might appropriately aspire. The SDS is probably the third most widely used device for measuring occupational interests.

Sexism and Racism in Measurement

All of these instruments have met with difficulties over the years as concerns about racial and sexual biases have heightened among test users. Most obvious in the earlier versions were sex bias leading to assumptions that particular occupations were deemed to be "male" as opposed to "female," which affected the construction of the questions, the norms for the instruments, and the language used to describe interests. Beginning in the 1960s, test users expressed concern that females who showed interest in traditionally male occupations would be inappropriately assessed using traditional instruments, as would males who expressed interest in traditionally female occupations. Since that time, most of the instruments have undergone a number of revisions and their language and normative approaches have been adapted to accommodate these critiques. The Kuder and Strong–Campbell measures now have same-sex and separate-sex normative approaches and sexism has been deleted from the language of the measures. Sexism is not a problem with the SDS, but there is a single set of norms, and, there are some systematic differences in the probability with which females versus males will score on different types that might not be related to eventual occupational membership and satisfaction.

Racism is more subtle and has been addressed less directly because the items are not necessarily racist themselves. However, the normative base, the language patterns, and the experience base is likely to be substantially different for various ethnic and racial groups. These factors may subtly affect the responses of individuals being assessed and their scores, resulting in potentially inappropriate inferences and interpretations of the results.

OCCUPATIONAL STRESS

Occupational stress arises from an interaction between people and their jobs and is characterized by changes within people that force them to deviate from their normal functioning. Most theories of occupational stress postulate that stress occurs when environmental stimuli, or workers' appraisals of those stimuli, contribute to changes in workers' well-being or normal behavior.

It is important to note that occupational stress is a related, though distinct, concept from job dissatisfaction. Stress and dissatisfaction can have distinct correlates, and the presence of either stress or dissatisfaction does not necessitate the existence of the other. Therefore, a worker who is not satisfied is not necessarily experiencing occupational stress or the manifestations of that stress.

Personal consequences of occupational stress (i.e., strains) include psychological, physiological, and behavioral responses. Anxiety, depression, boredom, somatic complaints, psychological fatigue, frustration, feelings of futility, emotional exhaustion, and anger represent deleterious psychological outcomes. Physiological outcomes to occupational stress include cardiovascular disease, gastrointestinal disorders, respiratory problems, headaches, bodily injuries, fatigue, and death. Examples of behavioral responses include poor job performance, job-related accidents, absenteeism, disruptive or counterproductive job behaviors such as stealing or spreading rumors, acts of aggression, smoking, turnover, and drug abuse. Organizational consequences of occupational stress include costs associated with absenteeism, tardiness, turnover, poor performance, litigation and settlements, and retirement and health care benefits. Importantly, the data regarding any particular reaction are generally sparse. It is safest to conclude, therefore, that occupational stress can adversely affect an individual's well-being; precisely how these negative outcomes may be manifested remains an open question.

Three general classes of stress-inducing stimuli (i.e., stressors) include organizational characteristics and processes, working conditions and interpersonal relationships, and job demands and role characteristics. Organizational characteristics and processes that lead to an unsupportive organizational climate, inadequate or complicated technological resources, a poor or inequitable pay structure, frequent relocations, poor communications, discriminatory or unfair treatment, ambiguous or conflicting task assignments, shift work, and inadequate feedback can yield occupational stress.

Stressors related to working conditions include crowding, a lack of privacy, noise, excessive temperatures, inadequate or flickering lights, and exposure to hazardous materials. However, the relationship between certain conditions, such as amount of privacy and noise, and resultant strains appears to be more complex, with findings supportive of a curvilinear relationship between the degree of the stressor and well-being. Interpersonal relationships at work characterized by a lack of recognition, acceptance, supportiveness, and trust, as well as those characterized by high levels of competition, mistreatment, harassment, discrimination, and conflict are regarded as stressful.

In terms of job demands, potential stressors include repetitive work, high levels of demand, unpredictability, low levels of control and autonomy, time pressures and deadlines, responsibility for others such as employees or clients, and a discrepancy between skill level and skill utilization. Finally, research on the roles people perform at work suggests that role conflict, role ambiguity, role under- or overload, role-status incongruency, and work-family conflict function as occupational stressors.

It is essential to note that these three classes of occupational stressors are not independent of one another; the existence of one type of stressor influences the likelihood that other types of stressors will be present. For example, characteristics of a particular occupation or organization will impact working conditions and job demands. Therefore, identifying and studying one stressor in isolation, without considering the context in which the stressor occurs, can lead to misleading conclusions.

In addition to the stress associated with work, the absence of work also can be stressful. Although the loss of work is potentially stressful for several reasons, most evidence indicates that the financial repercussions of unemployment are especially devastating to individuals.

Despite researchers' efforts to identify various stressors and strains, several factors contribute to the difficulty in understanding and predicting individuals' reactions to a particular stressor. First, individuals may differ both in their likelihood of encountering certain stressful situations and in their reactions to the same objective stimuli. Therefore, consideration of various characteristics of the individual as well as those in the objective environment is necessary. In particular, the personality trait of neuroticism (or negative affectivity) influences workers' reports of occupational stressors and strains. Although researchers continue to debate the precise mechanisms underlying the role of such individual differences, findings indicate that these traits impact individuals' susceptibility to, perceptions and appraisals of, reactions to, and ability to cope with objective stimuli.

The second difficulty in understanding and predicting occupational stress is appreciating the reciprocal relationship between work and other facets of workers' lives. Examining how work and nonwork-related stressors, strains, and coping mechanisms impact each other is essential in understanding the complexities of occupational stress.

Third, in recent years, researchers have begun to reveal the intricacy of stressor–strain relationships by demonstrating the inadequacy of treating either all stressors or all strains as equivalent or identical to one another. Current research focuses on psychological processes instead of simply the identification of various stressors and strains.

Three general types of organizational interventions exist to reduce occupational stress or mitigate the harmful effects of occupational stress. Efforts to restructure the workplace, redesign the nature of the work, encourage participative management, modify organizational policies and climate, practice team-building, and promote acceptance of diversity are examples of preventive interventions that take place at the organizational level. Preventive strategies that occur at the individual level include helping workers to manage perceptions of stress and perceptions of the work environment; engage in relaxation training; practice effective coping strategies; and participate in healthy physical, spiritual, or emotional outlets. The third and most common type of intervention involves the treatment of employees after they have experienced occupational stress. Examples of

these strategies include Employee Assistance Programs, medical treatment, and substance abuse counseling.

OLFACTORY CORTEX

One of the most evocative of senses, olfaction produces powerful responses in humans and is used as a primitive but potent form of communication among animals. It is important to sexual attraction and may provide an early alarm signal of potential danger, while disgusting smells may signal the presence of toxins or other contaminants. Brain areas subserving various olfactory abilities, such as olfactory acuity, olfactory identification ability, and olfactory memory, may be differentially affected in various disease states.

Neuroanatomy of Olfaction

The mucous-lined olfactory epithelium of each nasal cavity consists of approximately 50 million receptor cells, which are bipolar neurons having short peripheral dendrites and long central axons. The dendritic processes connect to the mucosal surface, ending in an expanded olfactory knob from which extends a dense mat of cilia that interact with odorants entering the nasal cavity. The olfactory information is conveyed centrally via the axonal processes, which pass through the skull's cribriform plate to the ipsilateral olfactory bulb, situated beneath the orbitofrontal cortical surface. Unlike most sensory systems, there is no direct projection from primary olfactory receptors to neocortex. Neurons then project to *allocortical* (including the hippocampus, pyriform, or primary olfactory cortex) and *paralimbic* (including the orbitofrontal cortex, insula, temporal pole, parahippocampal gyrus, and cingulate) areas.

Olfactory information from each olfactory bulb has five important projections (Kandel, Schwartz, & Jessell, 1991; Pribram and Kruger, 1954). Each bulb communicates with the contralateral olfactory nucleus via the anterior commissure (Powell, Cowan, & Raisman, 1965), allowing rapid cross-hemispheric integration. Further projections pass via the ventral striatum (olfactory tubercle) and medial dorsal nucleus (MDN) of the thalamus to the orbitofrontal cortex (OFC; Potter & Nauta, 1979; Powell et al., 1965). The OFC mediates conscious appreciation and identification of odor (Eichenbaum, Shedlack, & Eckmann, 1983) and is relevant to cognitive aspects of smell (Potter & Butters, 1980), including sensory integration (Harrison & Pearson, 1989). Other axons from the olfactory tract radiate ipsilaterally to the anterior perforated substance and terminate in the amygdaloid complex. Further projections to hypothalamus and midbrain are considered relevant to eating and reproduction (Harrison & Pearson, 1989). Projections from the olfactory bulb also radiate to the pyriform cortex, which subserve olfactory recognition and discrimination, and then pass to the amygdala and the entorhinal cortex. The entorhinal cortex also receives direct projections from the olfactory bulb, where odor information is integrated with other sensory modalities. Polysensory information is then conveyed to the hippocampus. Limbic projections from the olfactory tract are relevant to the affective associations of odors and olfactory memory as well as to odor detection (i.e., olfactory acuity) (Potter & Butters, 1980).

Assessment of Olfaction

The assessment of olfactory function is undertaken using various odorants. *Identification ability* is assessed using scratch-and-sniff "suprathreshold" odors that are microencapsulated and embedded in plastic capsules coated onto labels, as in the standardized University of Pennsylvania Smell Identification Task (UPSIT; Doty, Shaman, & Dann, 1984). *Olfactory acuity* (or *detection*) is assessed using a forced-choice method utilizing graded concentrations of selected odorants that do not produce a trigeminal nerve response (Doty, Gregor, & Settle, 1986). *Odor discrimination* involves assessment of whether odors are the same or different without requiring identification. *Odor recognition* establishes whether an odor has previously been experienced, while *odor memory* requires recall of a previously presented target odorant from a series of odors (Martzke, Kopala, & Good, 1997). Assessment of olfaction in females should consider variations in olfaction with the menstrual cycle, while some steroidal substances may not be detectable by a significant proportion of the population (Albone & Shirley, 1984). Further, the assessment of olfactory function should take into account the decrease in olfactory threshold and identification ability with age (Doty, 1989).

Disorders Affecting the Primary Olfactory Sensory Organs

Temporary or prolonged reduction of olfactory acuity (hyposmia/anosmia) is often caused by diseases affecting the nasal mucosa or epithelium, including allergic, infective, or vasomotor rhinitis. Congestion and swelling of mucous membranes may also result from metabolic and hormonal disorders (Adams & Victor, 1981). As well as acting peripherally on nasal mucosa and epithelium, solvents can interfere with odor identification and odor detection through their action on the central nervous system (Schwartz, Ford, Bolla, Agnew, & Bleeker, 1991). Permanent loss of smell ability may result from exposure to toxins, from influenza

and upper respiratory infections, or from traumatic brain injury (TBI). Olfactory deficits due to TBI generally signify orbitofrontal damage, shearing of the olfactory bulbs, or damage to the delicate filaments of the epithelium (Adams & Victor, 1981).

Olfaction in Neurological Disorders

Findings from lesions studies suggest that lesions of the orbital prefrontal regions result in olfactory identification deficits, while olfactory acuity is spared (e.g., Jones-Gotman & Zatorre, 1988). Further, findings of more dramatic olfactory impairment following prefrontal lesions rather than damage to midline structures (e.g., thalamus) are consistent with a hierarchical organization of processing from medio-dorsal thalamic nucleus to entorhinal cortex and then to lateral posterior orbitofrontal cortex (Potter & Butters, 1980).

Studies in temporal lobe epilepsy (TLE) report reductions in olfactory acuity in patients with right temporal lobectomies (Martinez et al., 1993), while olfactory recognition, discrimination, and short-term memory ability are impaired in patients presurgery (Jones-Gotman et al., 1997; Martinez et al., 1993). Discrimination and short-term memory deficits are greater after temporal lobectomy (Martinez et al., 1993). Olfactory identification is relatively preserved in TLE patients presurgery; however, deficits are observed in lobectomized patients with lesions involving the OFC (Jones-Gotman & Zatorre, 1993).

Deficits in olfaction (acuity, memory, and identification) appear early in the course of a number of neurodegenerative disorders, including cortical Dementia of the Alzheimer's Type, and some of the subcortical dementias, namely Parkinson's disease, Huntington's disease, and HIV-related dementia. However, such deficits have not been reported in patients with atypical parkinsonian syndromes, including corticobasal degeneration and progressive supranuclear palsy (see Doty, 2001; Pantelis, Brewer, & Maruff, 2000). These findings are consistent with the nature of involvement of the relevant olfactory circuits in these various disorders, and suggest that smell ability may assist in differential diagnosis. Studies have also found deficits in olfactory memory in chronic alcohol abusers and of identification ability in patients with Korsakoff syndrome (Potter & Butters, 1980). Olfactory identification deficits have also been found in motor neuron disease (MND), multiple sclerosis (MS), and Down syndrome (McKeown et al., 1996).

Olfaction in Psychiatric Disorders

Olfactory deficits are not a prominent feature of depression, consistent with functional imaging studies finding dorsolateral rather than orbitofrontal cortex involvement (see Pantelis et al., 2000). This suggests that olfaction may help to discriminate depressive from dementing disorders (Doty, 2001). Patients with Obsessive-Compulsive Disorder show marked deficits in olfactory identification ability (Barnett et al., 1999), also implicating OFC involvement. Patients with schizophrenia consistently demonstrate deficits of olfactory identification ability and olfactory recognition memory (Moberg et al., 1999), with deficits in identification being found from illness onset, including neuroleptic naive patients (Brewer et al., 2001; Kopala, Clark, & Hurwitz, 1993).

Summary

Olfactory deficits are observed in a number of neurological and psychiatric disorders. Such deficits involve different aspects of olfactory function, which depends on the nature and extent of neurological involvement. There is evidence to suggest that olfactory functions may be dissociable, with the most profound deficits seen in higher order function involving the ability to identify odors, which implicates orbitofrontal cortex involvement. Examination of olfactory disturbances may provide early markers of impending neurological or psychiatric illness and, in some psychiatric disorders including schizophrenia, may be trait markers of the condition.

OPERANT CONDITIONING

Operant conditioning, a term coined by B. F. Skinner in 1937, has several shades of meaning. It is both an experimental procedure and a behavioral process, that is, a characteristic interaction of an organism and its environment observed in species with complex nervous systems. In the latter sense, it is a biological adaptation with a plausible evolutionary interpretation. The study of operant conditioning and related phenomena comprises a substantial research paradigm within psychology in both laboratory and applied settings. This paradigm endorses tightly controlled experiments to discover behavioral principles; the direct extension of those principles to behavior therapy, education, organizational behavior management, and other applications; and the use of the principles as interpretive tools for understanding complex human behavior such as language, memory, and problem solving.

The Operant Conditioning Procedure

In an operant conditioning procedure, a consequence is made contingent upon a behavior; specifically, the experimenter arranges a contingency in which a stimulus is presented if and only if a target behavior has just occurred. For example, an apparatus might be arranged so that, whenever a rat presses a lever, a drop of water drips into a dish from which the rat can drink. If the rat has recently been denied access to water, the strength of the target behavior will change; among other effects, the rate of pressing the lever will increase in that setting and in similar settings. If replications and suitable control conditions demonstrate that this change in strength is in fact due to the contingency, and is not a coincidence, the procedure is an instance of positive reinforcement, and water is called a reinforcing stimulus. If the rat has not been deprived of water, the procedure might have no effect on behavior. Under these conditions, if the rat were forced to drink by squirting water in its mouth, for example, we would expect the rate of lever-pressing to decrease relative to a baseline condition. We then speak of a punishment contingency and of water as a punishing stimulus. Thus both reinforcement and punishment are defined, not by procedures or by the nature of particular stimuli, but by their effects on the probability of behavior under given conditions.

Although Thorndike was the first researcher to study operant conditioning systematically, Skinner was the first to discover that the rate of behavior in freely moving organisms was highly sensitive to a wide variety of independent variables. In experiments using Skinner's methodology, the demonstration of operant principles has been found to be highly reliable in many species. Single-subject designs are preferred, since the behavioral principles of interest are revealed in the detailed interactions of organism and environment and may be obscured by averaging cases. Skinner recognized that appropriate units of analysis in psychology should not be defined in advance by the experimenter, but

should be determined empirically, by looking for orderly relationships between the organism and its environment. The units that emerge from such an analysis are three-term contingencies of environment, behavior, and consequence, and no one term can be understood in isolation.

Operant Conditioning as a Behavioral Process

Operant conditioning procedures have revealed that behavior changes in strength or probability when it is followed by biologically important consequences such as access to food, water, sexual activity, or escape from painful stimuli, cold, or excessive heat. Activities that tend to promote survival and reproduction become more frequent, while those that bring harm are reduced or eliminated. Operant conditioning is thus an evolutionary adaptation enabling an organism to adjust to variable environments where nourishment, comfort, potential mates, and danger are not ubiquitous but must be searched for, fought for, or avoided. Food, water, and sexual contact are all examples of unconditioned reinforcers, stimuli that are innately reinforcing under relevant motivating conditions. However, neutral stimuli can acquire a reinforcing function if they are frequently paired with unconditioned reinforcers. Thus we learn to respond to the dinner bell, to hunt for a water fountain, and to approach a member of the opposite sex who smiles at us. In humans, money, fame, and prestige are particularly effective conditioned reinforcers only indirectly related to survival and differential reproduction.

The strengthening of adaptive behavior and the weakening of ineffective behavior is a selection process, analogous in many respects to natural selection. Behavior is variable; even a highly practiced behavior will vary somewhat from one instance to the next. By differentially reinforcing responses with some property, such as relatively forceful lever presses, an experimenter can effect a change in the distribution of responses. More and more forceful lever presses occur to the point that the typical response is wholly unrepresentative of the original distribution of behavior. When organisms are exposed to such programs of gradually changing contingencies—a process called shaping—behavior can evolve and become highly differentiated over the lifetime of the individual, much as the morphology of organisms changes over evolutionary time. The repertoires of the skillful juggler, rock climber, and gymnast have presumably been shaped mainly by programs of intrinsic contingencies, but the repertoires of the seeing-eye dog, the race horse, the mathematician, the engineer, and the historian are likely to have been shaped mainly by programs of contingencies explicitly arranged by trainers or educators.

The Domain of Operant Conditioning

Some response systems, such as respiration, circulation, and digestion, serve a narrow function in the economy of the organism, and it would not be adaptive for them to vary substantially with arbitrary contingencies of reinforcement. In contrast, the orientation of receptors and responses mediated by skeletal muscles, such as the vocal apparatus, limbs, digits, and other effectors, can be recruited for a wide variety of tasks. Operant conditioning can most easily be demonstrated in the latter class of response systems.

It is characteristic of students of operant conditioning to confine their experimental analyses to objective, measurable variables. However, in any experiment some part of the behavior of an organism is always below the threshold of observability. Since this threshold depends upon the tools of the investigator and is not an intrinsic property of behavior, it must be assumed that the principles of operant conditioning apply not only to behavior that can be observed, but also to covert behavior as well. The psychologist's understanding of covert behavior is necessarily interpretive rather than experimental. The principle of reinforcement has proven a powerful tool in such interpretations since the terms of the analysis have been well established in single subjects under analogous conditions in the laboratory. However, the extent to which operant conditioning and other principles of learning provide a sufficient foundation for an interpretation of such phenomena as language, recall, covert problem solving, imagery, and perception remains controversial. Behaviorists argue that these phenomena can all be interpreted with established principles of learning. From this perspective, operant conditioning is the primary principle underlying all adaptive complexity in behavior.

OPERATIONAL DEFINITION

Few topics in the area of scientific communication have been as troublesome as that of operational definition. Psychologists have done their share both to clarify and to muddy the waters on this problem, and this article outlines some of the principal facets they need to consider.

Operationism

Operationism was initiated by Harvard University physicist P. W. Bridgman, who had reviewed the history of definitions of fundamental physical concepts like length, space, and time as they were used before Einstein to learn why they required such drastic revisions in Einstein's revolutionary theorizing. Bridgman concluded that the traditional Newtonian definitions had contained substantial amounts of meaning not related to their actual physical measurements (e.g., the assumption of an absolute scale for time); it was this kind of excess meaning that was responsible for Einstein's need to make radical reformulations in these concepts.

Bridgman suggested that to avoid similar roadblocks in the development of physical theory it would be necessary to impose more stringent requirements on the making of definitions. His proposal was that concepts should be defined strictly in terms of the operations used to measure them. As he put it, "The concept is synonymous with the corresponding set of operations."

Bridgman found that nothing was quite as simple and straightforward as it had seemed at first. He subsequently made some strategic retreats from his initially monolithic position, such as acknowledging at least the temporary admissibility of paper-and-pencil operations and accepting the usefulness of abstract concepts.

The idea that the meaning of all concepts should be restricted to the necessary operations underlying them had an immediate appeal for psychologists. Operationism was promulgated early in psychology by S. S. Stevens. Stevens was careful to point out that the operational-definition movement was simply a formalization of the methodology that had always been used by effective scientists, including psychologists.

Unfortunately, the balanced position advanced by Stevens did not quite prove to be the norm. Probably the single most important negative factor was the overselling of the operational ideal, especially as applied to situations in which perfectly operational definitions of psychological concepts were clearly not even approximately feasible. Also, there was the continuing persistence of the more grandly conceived operationism, and the consequent overloading of what should have been merely a fundamental methodological principle with essentially fewer relevant substantive issues of one kind or another. The net result has been that far too little attention has been paid to the central principle.

A good example of the communication difficulties that await the unwary user or reader is afforded by the word *frustration.* Quite apart from the further complications of theoretical nuances, this word is used in at least three distinct ways, which are usually but by no means always kept clearly separated: (a) as a kind of blocking operation that prevents a motivated organism from obtaining a goal or persisting in goal-directed behavior; (b) as the kind of behavior that appears when such a goal-oriented organism is thus blocked; and (c) as some hypothetical inner process that is assumed to be responsible for the overt behavioral responses to the blocking operation.

None of the secondary and tertiary disputes over operationism can eliminate the fact that psychologists all too often simply fail to communicate adequately with each other because they continue to use key terms in a variety of loosely defined and highly ambiguous ways. Some basic considerations need to be emphasized. First, operational definitions are not all-or-none achievements; rather, there is a continuum of operational clarity in definitions, that is, in the degree to which ambiguity and excess meaning have been eliminated. Second, full operational clarity needs to be an objective to be kept clearly in mind throughout all phases of theoretical and empirical research; acceptance of ambiguity must be regarded in many situations as a necessary but, it is hoped, not a permanent condition, and it is important that scientific communicators explicitly recognize this state of affairs rather than simply ignore it and gloss over the problem. Third, substantive issues involving defined concepts must not be allowed to intrude on and confuse the primarily methodological criteria associated with operational definitions. Fourth, it is hoped that recognition of the importance of these considerations serves as a spur to improve definitional clarity and ultimately to help make improvements in theoretical development. Taking this kind of positive approach to the definitional problem should also serve to help free psychologists from the semantic quagmires in which so many of the key concepts are still entangled.

OPERATIONALISM

Operationalism is the demand that theoretical terms in science—that is, those that do not refer to something directly observable—be given operational definitions. Operational definition was proposed independently by the physicist Percy Bridgman (who named it) and by the logical positivists, who called it "explicit definition." It was introduced

to psychology by S. S. Stevens in 1935, and played an important role in behaviorism. The goal of operationalism was to eliminate from science any concepts that were metaphysical, and to positivists meaningless, ensuring that science would ask only questions that had empirical answers, and would have theories that referred only to meaningful entities.

As empiricists, operationists assume that we can never be in doubt when talking about things we can observe. Thus, the meaning of an observational term such as "red" is unproblematic because it refers to a publicly observable attribute of objects. Uncertainty arises for theoretical terms such as "mass," "drive," "anxiety," and "superego." None of these is publicly observable, even though we have all experienced anxiety or hunger, while two terms, "mass" and "superego," may turn out not to refer to anything at all. Nevertheless, science needs theories and theoretical terms, and operationalists sought to guarantee the cognitive significance of theoretical terms by giving each an operational definition. In an operational definition, we define a theoretical term by linking it to some publicly verifiable operation—a measurement or a manipulation—we can perform on the environment. "Mass" becomes the weighing of an object at sea level, "drive" the withholding of food from an animal for some number of hours, and "anxiety" the score of a subject on the Taylor Manifest Anxiety Test.

The operationalist contends that the operational definition supplies the full meaning of a concept by linking it to unproblematic observation terms; anything more is unscientific surplus meaning. Moreover, operationalists question the scientific legitimacy of any term not operationally definable. Thus, the Freudian concept of the superego might be challenged as hopelessly unscientific, as there is no clear way of defining it in terms of something observable.

Operationalism gained wide assent in psychology, and, despite the death of logical positivism, psychologists continue to use operational definitions for theoretical terms that otherwise might have only mental, nonpublic, and therefore, psychologists fear, nonscientific meanings. Nevertheless, operationalism has been controversial. It has proved difficult, if not impossible, to operationalize all the terms even of physics, leading positivists themselves gradually to abandon operationalism. In psychology, operationalism has been criticized for unduly narrowing psychology's focus, making behaviorism the only acceptable psychology by methodological fiat rather than by superiority of results. That terms be operationalized remains, however, a common requirement of psychological theory.

OPIOID RECEPTORS

The effects of opiates, such as heroin or morphine, are consequences of the interactions of these drugs with opioid receptors. Opioid receptors, like receptors for other neurotransmitters, are cell surface proteins that (1) detect the presence of specific neurotransmitter or drug molecules in the extracellular environment, and (2) initiate biochemical changes that alter cellular processes in response to neurotransmitter or drug binding to the receptors. The activation of opioid receptors results in hyperpolarization, reduced neuronal excitability, and the blockade of neurotransmitter release in cells bearing the receptors.

Receptors that specifically bind opiate drugs were demonstrated in 1973, and endogenous peptides that bind these receptors were subsequently purified from brain (Pert & Snyder, 1973; Akil, Watson, Young, Lewis, Khachaturian, & Walker, 1984). There are three major families of endogenous opioid peptides: the endorphins, the enkephalins, and the dynorphins. The terminals of neurons containing endogenous opioid peptides are distributed in the same areas of the nervous system where there are high densities of opioid receptors, and it is believed that the endogenous opioid peptides function as the neurotransmitters or neuromodulators that utilize the opioid receptors. While the specific functions of endogenous opioid peptides are incompletely understood, they have been implicated in a variety of central nervous system functions including nociception, homeostatic function, mood regulation, and reward.

There are three subtypes of opioid receptor, referred to as mu, delta, and kappa receptors. The subtypes are distinguished by distinct binding selectivities, patterns of distribution in brain and spinal cord, and functional properties. Each opioid receptor subtype can be further categorized into subtypes on the basis of binding selectivities, distribution, and function.

Opioid receptors belong to the superfamily of G protein-coupled receptors. G proteins become functionally activated in response to receptor activation and can then initiate functional changes. G proteins can directly influence proteins such as ion channels, and they can also indirectly influence protein functions by interaction with biochemical messenger systems. Opioid receptors couple to both types of G protein.

The most studied messenger system associated with

opioid receptors is the adenylyl cyclase (AC) enzyme that mediates the synthesis of cyclic adenosine monophosphate (cAMP). The cAMP acts as a biochemical messenger that activates cAMP-dependent protein kinase (PKA). PKA is an enzyme that adds phosphorylates to a variety of types of cellular proteins, thus altering their size, charge, and functional capabilities. Opioid receptors can activate an inhibitory G protein (G_i), which inhibits AC activity and cAMP formation and consequently decreases substrate phosphorylation by PKA. Substrates for PKA include neurotransmitter receptors, synaptic proteins, and neurotransmitter synthetic enzymes, all of which can modify neuronal excitability.

Opioid receptors are also coupled to G proteins that can directly regulate ion channel activity and cellular excitability independently of second messenger intervention. Opioid receptors regulate ion channels controlling K^+ and Ca^{++} currents though direct coupling with G proteins. The results of opioid receptor activation are increased K^+ outflow causing hyperpolarization of the membrane potential, and reduced Ca^{++} entry into cells (Duggan & North, 1983). These mechanisms are thought to be important to the opioid blockade of neurotransmitter release, which may be the primary mechanism whereby opiate drugs reduce transmission within pain pathways and produce analgesia.

Opioid receptors of each subtype have been cloned and sequenced in animals and humans (Knapp et al., 1995; Satoh & Minami, 1995). The amino acid sequences indicate that they all contain the seven hydrophobic membrane-spanning domains that are characteristic of the G protein coupled receptor superfamily. The sequences show significant homology, with the greatest homology in the transmembrane regions and in the intracellular regions that connect them.

The three opioid receptor subtypes show distinct patterns of distribution in the nervous system (Mansour, Khachaturian, Lewis, Akil, & Watson, 1988; Tempel & Zukin, 1987). Mu receptors are found in the dorsal horn of the spinal cord, the spinal trigeminal nucleus, periaquaductal gray, and medial thalamus, consistent with a role in morphine-induced analgesia. They are also found in brain stem nuclei that are involved in morphine depression of respiration and stimulation of nausea and vomiting. Mu receptors in the nucleus accumbens, ventral tegmental area of the midbrain are important to morphine effects on mood and reward.

Delta opioid receptors are more restricted in their distribution and are found mainly in forebrain structures (neocortex, caudate-putamen, and amygdala) and the spinal cord and are also thought to participate in analgesia. Kappa receptors are located in the dorsal horn of the spinal cord, and in the hypothalamus where they may regulate neuroendocrine function. Kappa receptors are located in amygdala, dorsal striatum, and in the nucleus accumbens, and in contrast to mu-mediated effects, kappa receptor stimulation can produce dysphoria and psychotomimetic effects.

OPPONENT-PROCESS THEORY OF EMOTION

The opponent-process theory of emotion was initially proposed by Solomon in 1970 as a general theory of motivation that focuses on the temporal pattern of changes in the qualitative nature and intensity of emotional/affective states (responses) evoked by sensory events (stimuli). Following an exemplary model developed by Hurvich and Jameson (1957) in their theory of color vision (especially complementary color afterimages), Solomon (1980; see also Solomon & Corbit, 1974) applied the opponent-process system in a parsimoniously elegant form to account for a broad range of psychological phenomena, chief among them addiction and aversion.

A description of the pattern of the affective dynamics underlying the theory begins with the introduction (onset) of either a pleasurable or aversive stimulus which evokes an affective/hedonic reaction (A State) that rises quickly to a peak. The intensity of the hedonic A State (affect/emotion/tone/feeling/mood) then declines to a steady level where it remains as a long as the stimulus quality and intensity are maintained. Immediately following the termination of the stimulus, its affective reaction ends and is replaced by a different affective afterreaction (B State) which is opposite that of the initial hedonic state (i.e., the B State is the opponent of A State). This afterstate (B State) reaches its peak at a slower rate than that of the A State, then decays at a

relatively slow rate until the initial neutral affective baseline is eventually reestablished.

An everyday example of the phases of the affective dynamics in the case of a hedonically positive A State (which implies a negative B State) and the events that evoke them might be as follows: News (stimulus) that a long-absent loved one will soon return evokes a positive hedonic state (A State) of joy or happiness (response). If the subject hears subsequent news that plans for the return of the loved one have been canceled, the positive A State will end abruptly and be replaced with a negative hedonic B State of sorrow or unhappiness, which will gradually decay until the neutral hedonic state extant prior to the positive news is reestablished. An example of the affective dynamics in the case of a hedonically negative A State might be one in which news (stimulus) that a loved one is seriously ill evokes a negative hedonic A State of sorrow or unhappiness (response). If subsequent news announces that the diagnosis was in error, the negative A State will end abruptly and be replaced with a positive hedonic B State of joy or happiness which decays gradually until the prior hedonically neutral state returns.

Beyond typical hedonic theories that assume events arouse positive or negative states, the opponent-process theory of emotion proposes that hedonic (affective/emotional) states are automatically opposed by self-regulatory negative feedback loops within the central nervous system, that is, opponent *processes* that reduce the intensity of their respective hedonic *states.* If the A State is positive, its underlying *a* process is opposed by a negative *b* process; and if the A State is negative, its underlying *a* process is opposed by a positive *b* process. Thus, in addition to the "baseline-A-B-baseline" sequence of emotional states illustrated above, the theory posits that each emotional state is accompanied by underlying opponent processes. The intensity and duration of affective states is determined through an analysis of these underlying affective processes. Arousal of the *a* process is accompanied by arousal of its opponent *b* process, a slave process that is slow to rise and slow to decay. The difference between these two processes determines the hedonic quality of emotional experience. (If $a > b$, then the organism is in the A State; and if $b > a$, the organism is in the B State.) Because the *a* process ends abruptly with the termination of the stimulus for the A State, and because the *b* process is slow to decay, the termination of the stimulus for the A State will give rise to an opposite or opponent affective state. With frequent arousal of the A State, the *b* process will increase in magnitude and duration, thereby diminishing the intensity of the A State proportionately.

Although the theory does not depend on assumptions of associative learning to account for positive and negative reinforcement effects often applied in theories of addiction, the affective A and B States are subject to Pavlovian/classical conditioning. Thus, the theory accounts for addictive behavior in the absence of any apparent current pleasurable consequences of the addictive substance by pointing to the increase in intensity of the negative B State that accompanies withdrawal from the addictive substance (stimulus for A State) and by pointing to the conditionality of both the A State and the B State. According to the theory, associative processes, though present in cases of acquired motivation, are neither necessary nor sufficient to produce related behaviors. Addictive behaviors are representative of most acquired motives in social contexts. In acquired motivation, affective processes are inevitably involved: namely, contrast, habituation, symptoms of withdrawal, and opposition between states characteristic of the presence or absence of the stimuli.

In the study of addiction, a critical assumption of the theory lies in the effects of frequency of stimulus occurrence (use of addictive substance) and latency between doses on the changes in the intensity and duration of B States (and their underlying b-processes) relative to A states (and their underlying a-processes). According to the theory, the opponent process *b* is strengthened by use and weakened by disuse, whereas the primary affective process *a* is not significantly affected by use. As such, with frequent elicitation, the b-processes will show a shorter latency of response, sharper rise time, greater asymptote, and slower decay time than *a* processes. The effect on hedonic response rate after many stimulations will be a lower peak of the A state (labeled A'), and a more intense, longer-lasting B state (labeled B'). In time the addictive substance (stimulus for A State) offers the addict nothing but relief from the aversive effects of its absence. Because the theory is nonassociative, a major implication of the postulation of opponent-processes is that physiological stress can be caused by pleasurable as well as aversive stimulation. Thus, one should look for disorders of adaptation to types of stresses due to correlated physiological side effects of long duration and often-elicited intense *b* processes.

The theory provides a unique model for understanding a broad range of emotional/motivational phenomena; it is a singular contribution to the behavioral sciences, especially psychology, psychiatry, and psychophysiology. For examples of how the opponent-process theory has been applied in clinical respiratory psychophysiology to account for the anxiolytic effects of single inhalations of large concentrations of carbon dioxide (Wolpe, 1987) and amyl nitrite (Wolpe, 1990), see Ley (1994).

OPPOSITIONAL DEFIANT DISORDER

Oppositional Defiant Disorder (ODD) is a recurrent pattern of negativistic, disobedient, and hostile behavior toward authority figures (American Psychiatric Association, 1994). A diagnosis requires that at least four of eight symptoms are present over the course of at least six months. Symptoms include: (1) losing one's temper, (2) arguing with adults, (3) actively defying adults' requests or rules, (4) deliberately annoying others, (5) blaming others for mistakes, (6) being easily annoyed, (7) being angry and resentful, and (8) being spiteful or vindictive (American Psychiatric Association, 1994). Those receiving a diagnosis of ODD exhibit such behaviors at a frequency above what is considered to be developmentally appropriate, and such behaviors lead to significant impairment (e.g., in social or academic functioning). These symptoms need only be present in one setting to receive a diagnosis, and children sometimes exhibit symptoms in the home setting without concurrent problems at school or in the community (American Psychiatric Association, 1994). Estimated rates of ODD in the general population range from 6% to 10% (McMahon & Estes, 1997). Epidemiological research suggests that ODD may be more common in males than females, with gender differences more pronounced at younger ages (Lahey, Miller, Gordon, & Riley, 1999).

ODD involves a broad tendency to respond angrily (Lahey, McBurnett, & Loeber, 2000). Although children with ODD are often verbally aggressive, they do not display the frequent physically aggressive behaviors observed in Conduct Disorder (CD). In fact, these two diagnoses are mutually exclusive and, to be diagnosed with ODD, a child cannot also meet criteria for CD (American Psychiatric Association, 1994). However, Loeber (1990) hypothesized that aggressive behavior, including verbal aggression, in the elementary school years is part of a developmental trajectory that can lead to adolescent delinquency and CD. Indeed, a subset of children with ODD will proceed to develop CD, whereas some children will develop CD without ever meeting diagnostic criteria for ODD (American Psychiatric Association, 1994; Lahey et al., 2000). Longitudinal research indicates that ODD is a strong risk factor for CD in boys, whereas the presence of ODD does not increase the risk for later CD in girls (Rowe, Maughan, Pickles, Costello, & Angold, 2002). Girls with ODD, however, are at greater risk for continued ODD and internalizing disorders (Rowe et al., 2002). In general, children are more at risk for continued behavior problems if they display both overt and covert behaviors across multiple settings (Lochman & Szczepanski, 1999). Likewise, certain environmental risk factors, such as a dysfunctional family setting, socioeconomic disadvantage, or a violence-ridden neighborhood can play a role in moving children along this developmental pathway (McGee & Williams, 1999).

Precursors to ODD may start very early among inflexible infants with irritable temperaments (Loeber, 1990; Sanson & Prior, 1999). Likewise, early behavioral problems, such as impulsivity, overactivity, and mild aggression, may blossom into more serious forms of disruptive behaviors, including ODD (Sanson & Prior, 1999). Children with difficult temperaments and early emerging behavioral problems are at greater risk for failing to develop positive attachments with caregivers and becoming involved in increasingly coercive interchanges with parents and significant adults, such as teachers. Likewise, parents of children with disruptive behavior problems often display high rates of harsh, inconsistent discipline, have unclear rules and expectations, and have low rates of positive involvement, adaptive discipline strategies, and problem solving skills (Lochman & Wells, 1996; Patterson, 1986). Loeber (1990) hypothesized that children begin to generalize their use of coercive behaviors to other social interactions, leading to increasingly oppositional and disruptive behavior with peers and adults and to dysfunctional social–cognitive processes. These dysfunctional processes, in turn, serve to maintain problem behavior sequences. Children with ODD have been shown to use problem solving strategies that rely on aggressive solutions, have difficulties encoding social information accurately, and expect that aggressive solutions will work (Coy, Speltz, DeKlyen, & Jones, 2001; Crick & Dodge, 1994). Such difficulties have been documented as early as preschool and are not accounted for by comorbidity with other disruptive behavior problems, such as Attention-Deficit/Hyperactivity Disorder (Coy et al., 2001). Notably, children with ODD lack insight into their defiant behavior and usually justify their behavior as a reaction to unfair demands (American Psychiatric Association, 1994).

Historically, psychosocial treatment of oppositional, conduct-disordered children has been perceived to be difficult and not very productive. However, in recent years randomized clinical research trials have identified empirically-supported treatments for ODD and CD. Brestan and Eyberg (1998) have identified two parent-training intervention programs with well-established positive effects (Patterson, Reid, & Dishion, 1992; Webster-Stratton, 1994) and ten

other programs as probably efficacious for treating disruptive behavior disorders such as ODD. Treatment strategies aimed at parents (e.g., improving parental monitoring and improving consistency in discipline; see Eyberg, Boggs, & Algina, 1995; Peed, Roberts, & Forehand, 1977; Webster-Stratton, 1994; Wiltz & Patterson, 1974), as well as cognitive-behavioral treatments targeting children (e.g., problem solving skills training, anger management, and impulse control; see Feindler, Marriott, & Iwata, 1984; Kazdin, Siegel, & Bass, 1992; Lochman, Burch, Curry, & Lampron, 1984) have led to a reduction in behavioral problems and externalizing symptomatology in children, including those with ODD (Kazdin, 1998; Kazdin & Weisz, 1998; Silverthorn, 2001).

Treatment outcome research indicates that a combination of interventions for both parents and children may be the most efficacious in treating ODD. For example, behavioral parent training programs for parents of children with ODD are most effective when provided in combination with a child-focused problem solving skills training component (Behan & Carr, 2000). Group intervention programs, which are time- and cost-efficient, are usually as clinically effective as individually based programs in treating ODD (Behan & Carr, 2000). Intensive, comprehensive prevention programs have also been developed and evaluated with high risk children starting as early as first grade, and the results indicate that aggressive behavior and other symptoms associated with ODD and CD can be reduced through early intervention (Conduct Problems Prevention Research Group, 1999; Tremblay, LeMarquand, & Vitaro, 1999; Vitaro, Brendgen, Pagani, Tremblay, & McDuff, 1999).

OPTIC NERVE

The sensory visual system begins with light stimulation of the retinal photoreceptors. The information is transmitted to the retinal ganglion cells and then transits the orbit and the optic canal as the optic nerve. The information then crosses in the optic chiasm, synapses in the lateral geniculate, and projects to the striate cortex. The optic nerve is a tract that is myelinated by oligodendrocytes, and therefore is considered part of the central nervous system. The one million axons not only transmit information about light, contrast, and color but also participate in setting circadian rhythms via projections to the hypothalamus. An intact anterior visual pathway is essential for normal visual function and pupillary reaction.

Anatomy of the Retinal Ganglion Cells

The photoreceptors—the rods and cones—sense light and initiate the neuroelectrical signal, which is processed by the 12 retinal layers. The processed information is then transmitted to individual retinal ganglion cells. Each retinal ganglion cell then sends a myelinated axon to converge at the optic disc (the optic nerve head visible on retinoscopy). Ganglion cells in the macular region provide central vision and send their axons directly from the fovea to the temporal optic disc (the papillomacular bundle). Fibers from the peripheral nasal retina enter the nasal optic disc, while the temporal retinal fibers enter the superior and inferior aspects of the optic disc (superior and inferior arcuate bundles). The ganglion cell axons comprise the nerve fiber layer, which can be viewed with a direct ophthalmoscope. These fibers are best appreciated through a dilated pupil using green illumination. The surface nerve fiber layer derives its vascular supply from the central retinal artery and its branches. Pathologic states of the retina or optic nerve may result in nerve fiber layer loss (ganglion cell axon death) that allows a clearer view of the retinal vessels.

Anatomy of the Optic Nerve Head

The optic nerve head is divided into three regions: retinal (prelaminar), choroidal (laminar), and scleral (retrolaminar). The lamina cribrosa is a grouping of perforations in the choroid and sclera through which the retinal ganglion cells exit. Although there are regional density differences, the connective tissue forms a tight seal that prevents leaking except under very high pressure.

The optic nerve head is composed of ganglion cell axons and a laminar matrix of astrocytes, capillaries, and fibroblasts. The axons account for 90% of the optic nerve head. The size and exit angle of the scleral canal varies from individual to individual. It lies approximately 3 mm nasal to the fovea and is an optically blind region due to the lack of photoreceptors. This blind spot is present on all visual fields, covers at least 5 degrees of visual space and lies 15 degrees temporal to fixation. The central retinal artery is a branch of the ophthalmic artery and pierces the optic nerve sheath inferiorly at 10 to 12 mm behind the globe, then emerges at the center of the disc.

The prelaminar region of the optic nerve head receives blood supply from the four short posterior ciliary vessels. In contrast, the short posterior ciliary, peripapillary choroidal vessels, and pial arterial network (the incomplete circle of Zinn–Haller) perfuse the laminar aspect of the nerve.

Anatomy of the Optic Nerve

The optic nerve has three meningeal layers: the dura, the arachnoid, and the pia. The subarachnoid space is filled with cerebrospinal fluid that is continuous with the central subarachnoid space.

The optic nerve is 50 mm but individual variation is common. In addition to the one millimeter intraocular component (the optic nerve head), the optic nerve has three other portions: intraorbital, intracanalicular, and intracranial. The intraorbital optic nerve segment is the longest and is often serpiginous. The ophthalmic artery, a branch of the internal carotid artery just as it exits the cavernous sinus, perfuses the orbital portion. The intracanalicular portion lies within the optic canal formed by the lesser wing of the sphenoid bone, and receives perfusion from the ophthalmic and internal carotid arteries. The intracranial portion of the optic nerve continues as the optic chiasm and then the optic tracts. The intracranial aspect of the optic nerve has multiple vascular sources, including the internal carotid, anterior cerebral, anterior communicating, and ophthalmic arteries.

The orbital optic nerve is myelinated posterior to the lamina cribrosa and, by definition, extends from the globe to the optic canal. The 20 to 30 mm segment has a redundancy that allows marked proptosis (usually at least 9 mm) prior to tethering of the optic nerve, which may be visualized on neuroimaging. Just prior to entering the optic canal, the optic nerve is enveloped in the annulus of Zinn—a condensation of the tendonous insertions of the recti muscles.

The optic canal runs posterior and medial and has approximate dimensions of 10 mm long by 5 mm wide. The canal is thinnest medially where the optic nerve travels adjacent to the sphenoid sinus and posterior ethmoid cells. In addition to the optic nerve, the canal contains the ophthalmic artery and a sympathetic plexus. The periosteums of the sphenoid bone and the dura of the optic nerve are fused within the canal. The intracanalicular optic nerve is thereby tethered and prone to compression by any space-occupying lesions.

As the optic nerve exits the optic canal it ascends and converges posteromedially to form the optic chiasm. A majority (53%) of ganglion cell axons from the nasal retina cross in the chiasm and join the uncrossed temporal contralateral fibers. These fibers then continue hemi-decussated in the optic tract. The optic chiasm is adjacent to the floor of the third ventricle and inferior to the pituitary gland.

Most ganglion cell axons terminate in one of the six layers of the lateral geniculate, where information is processed and then projected to the visual cortex via the optic radiations. These axons contain visual and pupillomotor information, and some fibers ascend to the hypothalamus and contribute to circadian control of diurnal rhythms.

Common Pathologic States of the Optic Nerve

Optic nerve function can be impaired by changes in its blood supply, or by inflammation, demyelination, or compression. The hallmark of optic nerve dysfunction is the afferent pupillary defect (Marcus Gunn pupil). The involved optic nerve is not transmitting as much light to the visual pathways as does the optic nerve on the normal side, so the involved pupil does not constrict as briskly and redilates more readily. Other findings include impaired color vision, central visual acuity, and a visual field defect. The optic nerve head may be normal, edematous, or pale.

Acute ischemic optic neuropathy occurs in the patient's fifth or sixth decade, and characteristically presents with acute, painless, unilateral loss of vision that is noticed upon awakening. The optic nerve typically has sectoral edema and the most common visual field defect is inferior altitudinal loss. Most patients do not regain normal visual function. Aspirin should be prescribed to prevent contralateral involvement. A sedimentation rate should be obtained to rule out temporal arteritis. If systemic symptoms of malaise, weight loss, or temporal pain are present, a temporal artery biopsy should be performed.

Optic neuritis typically occurs in women in their second or third decade. The visual loss is acute and accompanied by pain that is exacerbated with eye movement. The optic nerve head is often normal, but the visual field is abnormal. An afferent pupillary defect is present unless the contralateral side has been previously damaged. Most patients begin to improve in six weeks and regain near-normal visual function. Recurrent bouts of optic neuritis or magnetic resonance imaging evidence of multifocal periventricular demyelination make the diagnosis of multiple sclerosis likely. Acute visual loss should be treated with a 3-day course of intravenous Methylprednisolone followed by an oral Prednisone taper. Oral corticosteroids alone are contraindicated because they increase the risk of subsequent episodes.

Compressive optic neuropathy may occur from intraorbital tumors, optic nerve tumors, intracranial expansions of the sphenoid wing, or increased intracranial pressure. Enlargement of the extraocular muscles—as seen in thyroid-associated ophthalmopathy—can also compress the optic nerve at the orbital apex. The most common orbital tumor in adults is the cavernous hemangioma. Other, less common masses include schwannomas, neurofibromas, lymphomas, and hemangiopericytomas. Optic nerve meningiomas typically occur in middle-aged women, while optic nerve gliomas present in the first decade without a gender predilection. Sphenoid wing meningiomas are much more common than either of these primary optic nerve tumors. Intervention should be considered when proptosis (globe protrusion due to tumor growth) is dramatic or visual function is significantly impaired. Intraorbital tumors can be surgically excised allowing preservation of vision. Optic nerve tumors, in contrast, can not be removed without resulting in complete visual loss. Sphenoid wing meningiomas are approached intracranially, but complete surgical excision is difficult. External beam radiation is useful for lymphomas, optic nerve meningiomas, and incompletely-excised sphenoid wing meningiomas.

Thyroid-associated ophthalmopathy presents with proptosis, double vision, and periorbital swelling. In less than 10% of cases, the optic nerve becomes compressed by the en-

larged extraocular muscles. Intravenous corticosteroids, external beam radiation, and orbital decompression have all been successfully used to relieve the pressure on the optic nerve.

Pseudotumor cerebri (intracranial hypertension) characteristically presents in young, obese women. Transient visual loss, double vision, and headaches precede visual loss. Bilateral optic nerve edema is present in most cases. Neuroimaging should be performed to rule out an intracranial tumor; a lumbar puncture is then performed to confirm elevated intracranial pressure. Diamox (1–2 g/day) is effective in controlling the symptoms and preventing visual loss. A Lumboperitoneal shunt or optic nerve sheath fenestration should be performed if medical management is inadequate.

OPTIMAL FUNCTIONING

The area of optimal functioning was introduced into modern scientific psychology by Marie Jahoda. This area of psychology is a scientific investigation of what the person is capable of becoming, of the best the person can be, and of the way the person can realize any number of personal potentials.

Self-Actualization

Abraham Maslow's (1971) investigation of optimal functioning asserts that there are two basic realms of human need. One, called the D or deficiency realm, is composed of the things we need to be functioning persons. These include the physiological needs such as food and water; the safety needs to be protected from chaos; the love and belongingness needs to be included in a group to protect us from loneliness; and our esteem needs for self-respect and self-esteem. These are needs that must be met for us to be adequate as human beings.

The B needs—our needs for self-actualization and our aesthetic needs—enable us to be self-actualizing human beings. Maslow posited that these B-level needs, or meta-needs, are just as necessary as the D-level needs. If D needs are not met, one becomes ill physiologically and psychologically. If the B-level needs are not met, one develops metapathologies. Following Maslow's lead, Shostrom (1962, 1975) developed two inventories to measure self-actualization. Building directly on Shostrom's work, Jones and Crandall (1986, 1991) developed a short (15-item) index. In contrast, Summerlin and Bundrick (1996) developed a brief index by going back to Maslow's concept of needs hierarchy.

For Maslow, self-actualized persons are aided in their development by intense moments of ecstasy, joy, and insight called peak experiences. There are moments of transcendence that take a person beyond self-actualization to what Maslow called the Z realm, a realm beyond the self that transcends both space and time. Recently, Csikszentmihalyi (1996, 1997) has expanded the notion of peak experience in his concept of "flow."

Beautiful and Noble Persons

Working within the tradition of Maslow's approach, Landsman (1974) developed a system for describing and empirically investigating the optimal functioning person, "the Beautiful and Noble Person." Landsman described his Beautiful and Noble Person as a self that proceeds from: (1) the passionate self, a self-expressive, self-enjoying state; to (2) the environment-loving self, where the person cares deeply for the physical environment and the tasks to be accomplished in the world; and finally to (3) the compassionate self, which enables the person to be loving and caring toward other persons. Working within the Landsman tradition, Privette (2001) has investigated positive and peak experiences in general, as well as in the specific areas of sports and athletic performance (1997) and business (Thornton, Privette, & Bundrick, 1999).

Fully Functioning Person

Rogers (1959, 1980) described his idea of the optimal functioning or, in his terms, "fully functioning" person. In contrast to Maslow, Rogers emphasized the process of being

fully functioning as it occurs moment by moment in every person's life, rather than being primarily concerned with describing characteristics of persons. Rogers's emphasis is on process, rather than structural components of the optimally functioning person.

Rogers starts with the assumption that all people have the capacity to actualize or complete their own inner nature. The key is for people to remain in contact with their deepest feelings, which Rogers called organismic experiences. These direct and deeper feelings can be symbolized accurately in the person's awareness or they can be distorted. Optimal functioning is promoted when the person is able to be fully aware of this deeper, direct organismic level. The person must be able to develop the kind of self that is able to be congruent with the person's own deep feelings or experiences.

Psychology of Optimal Persons

Another formulation of optimal functioning centering on the concept of process that emphasizes constant change is Kelly's (1980) formulation of the psychology of an optimal person. The unit of analysis is the personal construct, a bipolar meaning dimension a person might hold, such as seeing people as loving versus rejecting. The personality of the individual is made up of a number of these personal construct dimensions. Kelly's system of optimal functioning requires that each individual use his or her system of personal meaning in order to complete what he termed "full cycles of experiences." By this, he meant that each individual must create his or her own conceptions of the world in such a way that these conceptions are continually tested and reevaluated. The work within this framework has centered on ways to evaluate each of the steps and to promote a progression through these steps as elaborated by Epting and Amerikaner (1980). The concern in construct theory is with the way in which people invent or create themselves rather than with their uncovering or discerning an inner self.

Optimal Personality Traits

Coan (1977) undertook a multivariate study of optimal functioning persons, and later elaborated the theoretical implications of this work. In this empirical approach, Coan employed a battery of tests that included measures pertaining to phenomenal consistency, experience of control, scope of awareness, openness to experience, independence, self-insight, and various other aspects of attitudes, beliefs, and adjustments. The final factor analysis yielded 19 obliquely rotated factors, though no single general factor was found that could represent a global personality trait of self-actualization. Coan suggests, from his analysis as well as from readings of Eastern and Western theories, that five basic attributes characterize the ideal human condition: efficiency, creativity, inner harmony, relatedness, and transcendecy. In a similar fashion, Hanin (1995, 2000) has developed the concept of Zones of Optimal Functioning (ZOF) with regard to athletic performance, suggesting that the ZOF for each individual is unique and dependent on various factors and environmental influences. Recently, Kasser and Ryan (2001) have investigated the relationship between optimal functioning and goal setting with college students.

OXYTOCIN

Oxytocin is a peptide hormone and neuromodulator with a range of physiological and psychological effects related to reproduction and social behavior. Oxytocin is produced predominantly in the hypothalamus and oxytocin-containing nerve terminals project to the posterior pituitary for release into general circulation, where it acts as a hormone. Oxytocin plays important roles in regulating both the progression of labor and lactation. Oxytocin is the most potent uterotonic substance known, and pitocin, a synthetic oxytocin, is widely used by physicians to stimulate the progression of labor. Nipple stimulation during nursing stimulates synchronous firing of hypothalamic neurons via a reflex arch, resulting in the pulsatile release of oxytocin from the mother's pituitary gland. This elevation in oxytocin stimulates milk ejection by causing myoepithelial cells in the mammary gland to contract.

Oxytocin-containing nerve terminals also project to sites within the central nervous system, where it acts as a neuromodulator to affect emotionality and behavior. Oxytocin receptors are found in discrete limbic brain areas known to regulate behavior. Most of our understanding of the role of central oxytocin is derived from animal studies, and therefore the findings may or may not be relevant to humans.

Reproductive Behavior

In animal models, central oxytocin facilitates female sexual behavior, or receptivity. Receptivity in rodents is regulated primarily by the sequential actions of ovarian estrogen and progesterone. Estrogen increases oxytocin synthesis and the numbers of oxytocin receptors in regions of the hypothalamus involved in the regulation of sexual behavior. Oxytocin injections into the hypothalamus of estrogen-primed female rats facilitate female sexual behavior, while oxytocin antagonists block this behavior. Oxytocin may also play a role in sexual performance in males. For example, oxytocin levels in the cerebrospinal fluid are elevated after ejaculation in male rats and oxytocin injections decrease the latency to ejaculation. Oxytocin also stimulates the occurrence of spontaneous, noncontact penile erections in male rats. The role of oxytocin in human sexuality is unclear; however, plasma oxytocin levels increase during sexual arousal and peak at orgasm in both men and women.

Social Memory

Animals living in social groups must be able to recognize familiar individuals. Several studies have suggested a role for oxytocin in the formation or expression of social memory. In rodents, social memory is based primarily on olfactory cues and can be quantified by measuring the decrease in olfactory investigation after repeated exposure to the same individual. Low doses of oxytocin enhance the formation of social memory in rats. Mice lacking a functional oxytocin gene fail to recognize individuals even after repeated exposure, but display normal social memory after a single injection of oxytocin. It is not known whether oxytocin plays a significant role in social memory for species in which individual recognition is not based on olfactory cues.

Social Attachment and Affiliation

Strong social attachments are essential for successful reproduction in mammals. Oxytocin is involved in the formation of social attachments between mother and offspring, and in monogamous species, between mates. In many species, virgin females fail to display nurturing behavior toward infants, but females display extensive maternal care for their offspring beginning moments after giving birth. Virgin rats receiving oxytocin injections into the brain display nurturing behavior toward pups, while interfering with oxytocin transmission interferes with the normal onset of maternal care in parturient dams. Once initiated, blocking oxytocin transmission does not interfere with maternal behavior, suggesting that oxytocin is important for the initiation, but not the maintenance, of maternal behavior. In sheep, oxytocin is released in the brain within 15 minutes of delivery of the lamb. Infusion of oxytocin into the brain of an estrogen-primed ewe elicits full maternal responsiveness within 30 seconds. Oxytocin also appears to facilitate the selective bond between the mother and her offspring, probably through an olfactory recognition mechanism. Ewes will allow their own lamb to suckle while rejecting other lambs. Stimulating oxytocin release during exposure to an unfamiliar lamb stimulates the ewe to bond with that lamb even if she has previously bonded with her own lamb. It is unclear whether oxytocin significantly in-

fluences the mother–infant bond in humans, although correlational studies suggest that endogenous oxytocin does influence personality traits in postpartum women. Women who give birth by cesarean section have fewer oxytocin pulses during breastfeeding than those who give birth vaginally, and are less likely to describe themselves during the postpartum period as exhibiting a calm personality or high levels of sociality. In mothers delivering by cesarean section, oxytocin levels are correlated with the degree of openness to social interactions and with calmness.

Like the bond between a mother and infant, strong social attachments are formed between mates in monogamous species. Prairie voles are a monogamous species of rodent and have been extensively studied as a model for understanding the neural basis of monogamy. In the prairie vole, oxytocin plays a role in formation of the bond of the female for the male. Infusion of oxytocin into the brain of a female prairie vole even in the absence of mating results in the formation of a pair bond. Oxytocin also enhances nonsexual affiliative behaviors. For example, experiments examining the effects of central oxytocin on social interaction in rodents have shown that oxytocin increases the time spent in physical contact with other individuals. There is speculation that central oxytocin may underlie the reinforcing nature of positive social interactions.

The role of oxytocin in human social relationships remains to be determined. Sex in humans may play a role in strengthening the emotional attachments between partners, and vaginocervical stimulation, nipple stimulation, and orgasm, each components of human sexuality, facilitate oxytocin release.

Anxiety

Oxytocin reduces the physiological reaction to stressful situations. Lactating animals and humans exhibit a clear decreased response to stressors. Lactating rats show an attenuated elevation in stress hormone in response to white noise compared to virgins. Infusion of oxytocin in virgin rats also dampens the elevation of stress hormones in response to stress, suggesting that the increased oxytocin released during lactation may be acting to buffer the individual from environmental stressors. Oxytocin also has anxiolytic effects in behavioral assays of anxiety, such as the elevated plus maze.

Oxytocin is not known to be directly involved in any psychiatric disorders; however, some interesting correlations have been reported. Autism is a disease characterized by, among other symptoms, deficits in social reciprocity in humans. One study has found that autistic children have decreased levels of plasma oxytocin compared to age-matched control children.

P

PAIN: COPING STRATEGIES

From an early age, virtually everyone has experience with brief, relatively mild pain caused by cuts, insect bites, minor burns, bruises, toothaches, stomachaches, and routine medical and dental procedures. In addition to these relatively minor painful experiences, some individuals also will experience acute pain from major trauma, surgery, and invasive medical procedures. Others may even experience persistent pain such as chronic back pain, headaches, or pain secondary to chronic illness such as arthritis. Whenever a person is confronted with a painful situation, there are demands or requirements placed on that individual for certain responses. For example, a child receiving an injection must hold his or her arm still while a needle is inserted into the arm. Individuals spontaneously react in these situations and use various strategies to deal with pain and the demands of the situation.

Cognitive Coping Strategies

Mental strategies or ways to use thoughts or imagination to cope with pain are usually called *cognitive coping strategies.* Distraction involves thinking about other things to divert attention from pain and can be internal, such as imagining a pleasant scene, or external, such as focusing on a specific aspect of the environment. Reinterpreting pain sensations is imagining that the pain is something else, such as numbness or a warm feeling. Calming self-statements refers to statements that one might tell oneself to provide comfort or encouragement (e.g., "I know I can handle this"). Ignoring pain is denying that the pain exists. Wishful thinking, praying, or hoping involves telling oneself that the pain will go away some day by faith, an act of God, or something magical. Fear and anger self-statements are statements one might tell oneself that promote fear or anger, such as "I am afraid I am going to die." Catastrophizing refers to the use of negative self-statements and overly pessimistic thoughts about the future (e.g., "I can't deal with the pain"). Cognitive restructuring refers to a process of recognizing negative thoughts and changing them to more realistic and rational thoughts.

Behavioral Coping Strategies

Overt things that a person might actually do to cope with pain are called *behavioral coping strategies.* Increasing behavioral activity involves actively engaging in activities such as reading or visiting with friends to stay busy and unfocused on pain. Pacing activity involves taking regular, planned rest breaks to avoid overdoing and experiencing increases in pain. Isolation refers to withdrawing from social contact to cope with pain. Resting refers to reclining in bed or on the couch. Relaxation involves attempting to decrease physiological arousal by remaining calm and relaxing muscles. Relaxation also is sometimes referred to as a physiological coping strategy, because it may include direct physical benefits.

Some coping strategies are effective and facilitate good adjustment, whereas other strategies are ineffective and may promote additional pain and suffering. Although intuitively certain strategies appear effective and others seem ineffective, empirical studies are needed to demonstrate the relationship between coping strategies and adjustment. This is especially important because some strategies are effective in one situation but not the next, or for one person but not another.

Chronic Pain

Most individuals probably begin to develop strategies for coping with pain from an early age and from exposure to relatively minor painful experiences. Yet the research in this area has progressed almost backward, with initial studies focusing on coping strategies used by chronic pain populations such as patients with chronic back pain or pain secondary to disease (e.g., arthritis and sickle cell disease).

One of the first instruments designed to assess pain coping strategies systematically was the coping strategies questionnaire (CSQ) developed by Rosensteil and Keefe. The CSQ measures the frequency with which individuals use various cognitive and behavioral coping strategies to deal with pain. Research using the CSQ with chronic pain patients has found that pain coping strategies can be reliably assessed and are predictive of pain, psychosocial adjustment, and functional capacity. Chronic pain patients who are high on catastrophizing and perceived inability to control and decrease pain have higher levels of depression and anxiety and overall physical impairment. Chronic pain patients who take a more active approach to managing pain by using a variety of cognitive and behavioral strategies have been found, in at least some studies, to have better functional adjustment (i.e., remain more active in work and

social activities). These results have been replicated across several research laboratories and with several populations of chronic pain patients (chronic back pain, headaches, osteoarthritis, rheumatoid arthritis, and sickle cell disease).

Taken together, the studies with chronic pain populations have generally concluded that although there seem to be some positive effects due to active coping efforts, negative thinking appears to be a more potent adverse influence on adjustment. Also, longitudinal studies have shown that coping strategies measured at one point in time are predictive of adjustment at follow-up. Thus maladaptive copers may continue to be at risk for future adjustment problems.

Stability and Change in Coping Strategies

Because of the significance of coping style in adjustment to chronic pain, researchers have attempted to determine whether the strategies used by individuals to cope with pain tend to be stable or to change over time.

Two approaches have been used to study this issue. The first approach has been to compare coping strategies assessed during a baseline assessment to coping strategies measured at follow-up (e.g., 1 year later) with no systematic intervention occurring between the two assessment periods. Results have shown that without intervention, coping strategies are relatively stable over time, suggesting that some individuals persist in ineffective coping efforts. This stability in coping style appears to be unrelated to changes in disease severity. That is, although disease severity may lessen, this does not automatically translate into improved coping efforts, and even if there is an increase in disease severity over time, this does not necessarily mean that there will be further deterioration in adjustment. Although coping tends to be relatively stable, individuals who do become more and more negative in their thinking may experience even further deterioration in functional capacity and psychosocial adjustment over time.

The second approach to examining changes in pain coping strategies in chronic pain patients has been intervention studies. These studies have attempted to improve pain coping by training individuals in cognitive and behavioral pain coping skills. These studies have shown that with intervention, pain coping skills can be improved, and improvements in pain coping skills translate into improvements of psychosocial and functional adjustment. For example, in one study, Keefe and coworkers trained a group of patients with osteoarthritic knee pain to use relaxation, imagery, distraction, cognitive restructuring, and pacing activity. Compared with a control group, trained subjects had lower levels of pain and psychological disability. Furthermore, individuals in the pain coping skills group who had greatest positive change in their coping strategy use (i.e., increased perceived effectiveness) had the most improvements in physical abilities. Similar findings have been reported across several types of pain problems.

Taken together, these results suggest that without intervention, the strategies an individual uses to cope with chronic pain are relatively stable over time. Change in pain coping skills is possible, however, and cognitive-behavioral approaches appear to provide an effective means to train individuals with various chronic pain problems to use more effective coping strategies.

Acute Pain

Acute pain may result from events ranging from minor experiences to pain secondary to surgery or invasive procedures. As with chronic pain, when an individual is confronted with acute pain, he or she reacts spontaneously and uses various strategies to cope. Because acute pain situations are often also stressful and anxiety provoking, coping strategies used in these situations often include strategies to deal both with pain and with anxiety.

Among the earliest attempts to examine coping strategies used in acute pain situations were studies that described preoperative and postoperative adults as either active or avoidant copers. Active copers were considered persons who approached the painful stimulus (i.e., surgery) by seeking out information, dealing with it rationally, and using cognitive strategies to cope. Avoidant copers (or those high on denial) were those who preferred not knowing information about their surgery or medical procedure, and actually became anxious and experienced more pain when provided with information. Conclusions based on these early studies are limited, however, because studies often attempted to categorize subjects into one of these patterns of coping based on informal interviews of questionable reliability.

More recently, systematic measures for assessing pain coping strategies in acute pain situations have been developed. Butler and coworkers developed the Cognitive Coping Strategy Inventory (CCSI) for use with postoperative pain populations. The inventory consists of subscales that are similar to dimensions found to be important in the measurement of chronic pain coping (i.e., catastrophizing, attention diversion, and imaginative inattention). Items, however, are more relevant to the acute pain experience. Research using the CCSI has found that this questionnaire is reliable and valid, and that coping strategies used by postoperative patients to deal with pain are related to recovery. For example, adults who are high on catastrophizing have higher levels of pain and functional disability after surgery.

Childhood Pain

The investigation of coping strategies in children confronting painful experiences is a relatively new area of research. In contrast to the work with adults in which questionnaires are primarily used to assess pain coping, most studies with children use interviews and observational methods to examine pain coping strategies.

Interview studies have used both open-ended and semi-structured formats to gather information on how children experience pain and what they do in response to it. For example, Ross and Ross interviewed a large sample of school-age children and asked them about the strategies that they used to cope with pain. Some of the children had chronic diseases such as sickle cell disease or hemophilia, but most had no major medical problems and responded in regard to their coping with more minor pain (e.g., cuts and bruises). Responding to open-ended questions, few children reported using self-initiated strategies to cope with pain. Of the small proportion that reported using strategies, distraction, thought stopping, and relaxation were among the more commonly reported strategies.

Observational studies of children coping with pain have focused primarily on children's reactions to painful procedures such as burn therapy or cancer-related treatments (e.g., venipunctures, bone marrow aspirations). In these studies, observers record the frequency of behaviors exhibited by the child such as crying, seeking social support, information seeking, and verbal and motor resistance. Although these behaviors are usually considered a measure of distress, some of the behaviors also can be conceptualized as coping efforts exhibited by the child to manage the pain and stress of the situation.

A few recent studies have found that coping strategies could be reliably assessed using questionnaires in school age children. Using a modified version of the CSQ that was developed for adults, Gil and coworkers found that children who engaged in negative thinking and relied passively on strategies such as resting had more adjustment problems. This pattern of coping was associated with greater reductions in school and social activity, more frequent health care contacts, and more depression and anxiety. Children who took an active approach to managing pain by using a variety of cognitive and behavioral coping strategies were more active and required less frequent health care services.

The KIDCOPE developed by Spirito, Stark, and Williams is a questionnaire that has been designed specifically to assess coping strategies used by children to deal with stressful situations. The child identifies a recent stressful event to provide a context for responding to the coping strategy items. Given that pain is a common problem identified by children with medical problems, the KIDCOPE can be a useful instrument to assess pain coping strategies, especially because it is relatively brief and simple to complete.

Child Age and Sex

Although there appear to be almost no major differences in coping between girls and boys, differences in coping strategy use have been found across different ages. Older children tend to have more coping skills in their repertoire, especially more cognitive coping skills. Some data suggest that older children with chronic pain secondary to disease may rely more on negative thinking and passive coping strategies as they get older. By adolescence, some of their maladaptive coping patterns may become entrenched and resistant to change.

Parents

The relationship of the parent to coping and adjustment in children also has been a recent target of study. A number of studies have evaluated the effects of parent presence versus absence on child coping during painful procedures. Most of these studies have shown that although children exhibit less overt distress when their parents are absent, they may be physiologically and psychologically disturbed by their parents' absence and merely inhibiting their behavioral reaction. Thus, rather than removing the parents, researchers may need to investigate which behaviors of the parent are related to effective versus ineffective coping by children during painful procedures.

Coping strategies used by parents to cope with their own (the parent's) pain also may be related to adjustment in children with pain problems. One study found that parents who took an active approach to managing their own pain had children who remained more active during episodes of sickle cell pain. Furthermore, there appear to be significant relationships between pain coping strategies in parents and in their children, suggesting that children might learn how to cope with pain, in part, by observing their parents' reactions.

Clinical Implications

Coping skills training is now a regular part of most comprehensive approaches to chronic pain management. Multidisciplinary pain programs now often include groups or individual sessions in which patients are trained to use active coping skills and cognitive restructuring techniques to manage pain. Although this type of approach is not routine for the management of most acute pain problems, there is a growing recognition for the need to train coping strategies to those undergoing medical procedures. Perhaps the area that has received the most attention has been in preparing children for surgery or for repeated invasive medical procedures such as burn therapy or cancer-related treatments. Although this is usually not done until after the child has developed a significant problem coping with pain, some clinicians are beginning to recognize the need to help prepare children to cope with painful experiences before they become oversensitized.

PANIC DISORDER

Epidemiology and Course

Panic Disorder (PD) (with and without agoraphobia) is a debilitating condition with a lifetime prevalence of approximately 1.5% (American Psychiatric Association [ApA], 1994). Studies have demonstrated that this prevalence rate is relatively consistent throughout the world. Approximately twice as many women as men suffer from PD. Although PD typically first strikes between late adolescence and the mid-30s, it can also begin in childhood or in later life. Although data on the course of PD are lacking, PD appears to be a chronic condition that waxes and wanes in severity. Consequences of PD include feelings of poor physical and emotional health, impaired social functioning, financial dependency, and increased use of health and hospital emergency services.

Description

As defined in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (ApA, 1994), the essential feature of PD is the experience of recurrent, unexpected panic attacks. A panic attack is defined as a discrete period of intense fear or discomfort that develops abruptly, reaches a peak within 10 minutes, and is accompanied by at least four of the following 13 symptoms: shortness of breath, dizziness, palpitations, trembling, sweating, choking sensation, nausea/abdominal distress, depersonalization, paresthesias (numbness/tingling), flushes/chills, chest pain, fear of dying, and fear of going crazy or doing something uncontrolled. To warrant the diagnosis of PD an individual must experience at least two unexpected panic attacks followed by at least one month of concern about having another panic attack. The frequency of attacks varies widely and ranges from several attacks each day to only a handful of attacks per year.

The vast majority of PD patients seeking treatment present with agoraphobia. Agoraphobia is the experience of anxiety in situations where escape might be difficult or where help may not be immediately available should a panic attack occur. Common agoraphobic situations include airplanes, buses, trains, elevators, being alone, or being in a crowd. As a result of the anxiety experienced in these situations, individuals often develop phobic avoidance resulting in a constricted lifestyle. The severity of agoraphobia ranges from mild to severe.

Causes Of PD

Following is a brief review of some of the most promising theories about the causes of PD.

Genetics

One line of evidence for a biological etiology of PD comes from studies that demonstrate that panic tends to run in families. These studies have found that approximately one half of all PD patients have at least one relative with PD, that first-degree relatives of PD patients are approximately five times more likely to develop PD than first-degree relatives of normal controls, and that PD and agoraphobia with panic attacks are more than five times as frequent in monozygotic twins than in dizygotic co-twins of patients with PD (Woodman & Crowe, 1995).

Neurotransmitter Theories

Biological theorists attempt to provide an indirect link between PD and specific neurotransmitter systems by assessing the effects of drugs on these neurotransmitter systems. Specifically, they attempt to demonstrate that drugs used to treat panic increase the availability of a specific neurotransmitter or its metabolite, while drugs that induce panic decrease the availability of the same neurotransmitter. An association may also be established by demonstrating that antipanic drugs decrease the availability of a specific neurotransmitter while panic-provoking drugs increase the availability of the same neurotransmitter. Neurotransmitters commonly implicated in the etiology of PD include norepinephrine, serotonin, and gamma-aminobutyric acid (GABA; Papp, Coplan, & Gorman, 1992).

Psychological Theories of PD

Several proposed psychological theories of PD are well supported by empirical data. This suggests that psychological factors are central to the etiology and maintenance of PD.

The cognitive model of PD proposes that panic attacks occur when individuals perceive certain somatic sensations as dangerous and interpret them to mean that they are about to experience sudden, imminent disaster (Clark, 1986). For example, individuals may develop a panic attack if they misinterpret heart palpitations as signaling an impending heart attack. The vicious cycle culminating in a panic attack begins when a stimulus perceived as threatening creates feelings of apprehension. If the somatic sensations that accompany this state of apprehension are catastrophically misinterpreted, the individual experiences a further increase in apprehension, elevated somatic sensations, and so on, until a full-blown panic attack occurs.

Pure behavioral models focus on the fact that panic attacks and agoraphobia are maintained by negative reinforcement. That is, individuals prone to panic attacks and agoraphobia avoid anxiety sensations and situations that may provoke anxiety. This leads to increased sensitization to anxiety symptoms and fuels further avoidance. Support for this model comes from learning theory and animal stud-

ies, as well as from treatment studies demonstrating that exposure-based treatments in which patients confront sensations and situations that were previously avoided lead to improvement (Barlow, 2001).

Treatment

Psychotherapy, specifically cognitive-behavioral therapy (CBT), and pharmacotherapy have both been shown to be effective treatments for PD (Wolfe & Maser, 1994). CBT consists of a number of treatment elements including psychoeducation, monitoring of panic, cognitive restructuring, anxiety management skills training, and in vivo exposure. Support for the efficacy of CBT for PD treatment is provided by extensive studies yielding high-quality data.

Four classes of medications have been shown to be effective in the treatment of PD. These medications are *selective serotonin reuptake inhibitors, tricyclic antidepressants, benzodiazepines,* and *monoamine oxidase inhibitors.* Studies demonstrate that medications from all four classes have similar efficacy. The choice of medication for a patient depends on a consideration of possible side effects, medication cost, and other clinical circumstances.

Studies that examine the effectiveness of combining CBT and antipanic medication compared to each modality separately have thus far been inconclusive. However, conventional clinical wisdom suggests that a combination is at least equivalent to either modality alone.

PARADIGMS

Paradigms are rules or regulations that set boundaries and direct actions toward accomplishing a goal successfully (Barker, 1992, p. 32). Kuhn (1970), a scientific historian, focused the attention of the scientific world on paradigms; he believed paradigms fit only the physical scientific world. Paradigms in action amount to a basic set of ideas or concepts that directs an individual's behavior, thereby setting parameters for the individual's standard way of working, or progressing toward a goal. This pattern becomes an individual's way of doing something or solving a problem.

Paradigms are found in every culture. Norms within every culture govern the boundaries of accepted behavior and become the proper way of doing things. When pattern changes occur, thus deviating from the established operating norms of any given situation, Barker (1992, p. 37) referred to this as "a paradigm shift . . . a change to a new game, a new set of rules."

In every generation, changes have been initiated by nonconformists who took risks to make paradigm shifts, because paradigms encourage conformity and the paradigm shifts create confusion. A simple example of a paradigm shift is when a person requests pie instead of the usual cake for a birthday; breaking from the custom of a birthday cake is a paradigm shift.

Within Western culture, many paradigm shifts have occurred. During the early 1900s, the Wright brothers created a paradigm shift with their invention of the airplane. Traditionalists believed that if God wanted humans to fly, we would have wings. Paradigm shifts led to vast changes in communications after the 1940s. Telephone calls, which used to require cranking a box on a party line, were transformed to single-party lines, worldwide calling, car phones, cordless phones, cellular phones, 800 numbers, and so forth. Each improvement marked a paradigm shift. Paradigms themselves range from challengeable to unchallengeable, and may include theories, models, and standards as well as frames of reference, ideologies, rituals, and compulsions (Barker, 1992, p. 35).

Family Institution

Before the 1940s, only a small percentage of women were in the job market, mostly doing office work. The basic paradigm before World War II was that women belonged at home with the children and the men were the breadwinners. At the time, this was an acceptable way of life. By 1950, however, a paradigm shift occurred. More women were entering the professional world. Many women entered the labor market so the family could have "extras," but later the second income became a necessity to survive the economic crunch.

Religion

Many changes have taken place in religious practices, for example, in the Roman Catholic Church since Vatican II. These changes include praying the Mass in the vernacular, the concept of healing of reconciliation, one hour of fasting before receiving communion, fewer statues, face-to-face confession, and increased lay ministries. Such changes met with considerable resistance. Ritzer (1975), in his interpretation of Kuhn's original work, stated that "the paradigm that emerges victorious is the one that is able to win the most converts." As new concepts gain more followers, the resistance to paradigm changes decreases and acceptance emerges.

Cognitive Development

Some presently accepted theories of cognitive growth and development that were originally paradigmatic are those by Erik Erikson, Sigmund Freud, Jean Piaget, and Lev Vygotsky. Another paradigm concerning intelligence is mentioned by Woolfolk (1993, pp. 111–116), and is based on the theories of Alfred Binet, Charles Spearman, L. L. Thurstone, J. P. Guilford, Howard Gardner, Robert Sternberg, and other theorists. Each presents guidelines and boundaries in methodology, standards, models, and procedures, and each specialty is under the whole umbrella of intelligence.

Education

As the needs of a society change, the educational process must change with it, thereby creating a paradigm shift. According to Drucker (1989), traditional education was rather terminal, ending with the attainment of a diploma or degree. However, today, because of continuing rapid changes in technology, education can not terminate at the time of degree completion. Continuing education is required as a result of paradigm shifts. Every employing institution becomes an educational facility as well as a place of employment. Drucker (1989, p. 252) stated "That major changes are ahead for schools and education is certain—the knowledge will demand them and the new learning theories and technologies will trigger them."

Technology

The word *paradigm* is used in all aspects of life because all facets of life have certain boundaries or parameters. Paradigms related to technology are changing rapidly in this highly technological age. Frequently, the changes are so rapid that the paradigm effect does not fully occur because new paradigms are continually being adopted. Our society, as well as the rest of the world, has come a long way from the days of Thomas S. Kuhn's original concept of paradigms.

Naisbitt (1984) stated that our lives and our social institutions are being transformed by the acceptance of the paradigm shift and by the recognition that we must change in order to survive. The paradigm shift alluded to by Naisbitt has taken place much more quickly than anticipated because of the rapid advancements in technology. Peters (1988, p. 518) stated that "integrity has been the hallmark of the superior organization through the ages . . . today's accelerating uncertainty gives the issue new importance."

Paradigm Shifts Over the Past Ten Years

Technology is accelerating very rapidly, thereby creating new paradigms faster than we can understand the present ones. New developments in the field of medicine include laser surgery, lasik surgery (eyes), laparoscopy, appendectomy, cholecystectomy (gallbladder), and many other advances. These are done either on an outpatient basis or a one-day hospitalization. In computer science, the Internet provides such features as the ability to buy and sell instantly, the use of e-mail, and access from anyplace a computer is available. As for telephones, cellular phones are replacing standard phones because you can receive and make calls just about any place. These phones are very compact. Television digital satellite dishes are replacing cable television, and compact discs and digital video discs (DVD) are used with computers and recording apparatus. Music can be heard on the computer via the internet. The invention of the personal digital assistant (PDA) allows individuals to maintain a personal data base. The business world now consists of mergers and acquisitions, a global economy, downsizing, and many more changes. These are just a few broad examples of some new paradigms in the last ten years.

Conclusion

Barker (1992, p. 36) stated, "the interrelationship of all these paradigms is crucial to the success and longevity of any culture or organization." Some paradigms are accepted more rapidly than others. If the need is great for a change, the paradigm shift will emerge quickly.

Paradigm shifts have occurred throughout the centuries, since the beginning of recorded history. As new concepts and ideas emerge, paradigm shifts will continue to occur in order to meet ever-changing human needs.

PARADOXICAL INTERVENTION

Paradoxical interventions are psychotherapeutic tactics that seem to contradict the goals they are designed to achieve. For example, a therapist may prescribe that clients have an unwanted symptom deliberately or restrain them from changing. In the classic definition of a therapeutic double-bind or paradox, "an injunction is so structured that it (a) reinforces the behavior the patient expects to be changed, (b) implies that this reinforcement is the vehicle of change, and (c) thereby creates a paradox because the patient is told to change by remaining unchanged" (Watzlawick, Beavin, and Jackson, 1967, p. 241).

References to resolving problems with paradoxical interventions appear as early as the eighteenth century. In this century, Dunlap applied the technique of "negative practice" to problems such as stammering and enuresis. Rosen (1953), through "direct psychoanalysis," encouraged psychiatric patients to engage in aspects of their psychosis in order to prevent relapse, and Frankl (1960) used paradoxical intention to help his patients revise the meaning of their symptoms. The most influential literature on therapeutic paradox, however, derives from Bateson's 1952–1962 project on communication. Bateson, Jackson, Haley, Weakland, and others explored the role of paradoxical "double-bind" communications in resolving as well as creating problems. Influenced by systemic/cybernetic ideas and by the work of master hypnotist Milton Erickson, descendants of the Bateson project such as Haley, Weakland, Watzlawick, Fisch, and Selvini-Palazzoli and colleagues went on in the 1970s to develop family therapy models with paradox as a central feature. Around the same time, Frankl's paradoxical intention technique was adopted by behavior therapists who demonstrated its usefulness with specific symptoms such as insomnia, anxiety, urinary retention, and obsessions.

Although paradoxical interventions have been associated historically with particular theoretical frameworks, the current literature tends to treat them as techniques that can be applied and explained apart from the models in which they were developed. Indeed, paradoxical interventions cut across theoretical boundaries insofar as paradoxical elements can be found in virtually all schools of psychotherapy (Seltzer, 1986). Nevertheless, there are striking differences in how therapists of different theoretical orientations use paradoxical interventions. In comparing cognitive-behavioral and strategic-systemic approaches—the two frameworks most akin to therapeutic paradox—one finds that behavior therapists use "paradoxical intention" to interrupt within-person exacerbation cycles, while strategic-systems therapists use a wider variety of paradoxical interventions and more often focus on between-person (family) interaction. Another difference is that behavior therapists make their rationale explicit, while strategic therapists typically do not. In behavioral applications of paradoxical intention, for example, the therapist teaches the client to adopt a paradoxical attitude, explaining, for example, how the client's intention to force sleep is actually exacerbating the problem, and why a paradoxical intention to stay awake might make sleep come easier. The *intention* here is clearly the client's, not the therapist's, and the client is expected to do (or at least try to do) what he or she is told. In strategic applications, however, the therapist sometimes expects a patient or family to do the opposite of what is proposed, and in this sense the therapist's intention is paradoxical. In contrast to the openly shared, educational rationale of a behavior therapist, strategic therapists attempt to maximize compliance (or defiance) by framing suggestions in a manner consistent (or deliberately inconsistent) with the clients' own idiosyncratic world view (Fisch, Weakland, & Segal, 1982).

Types and Applications

Several schemes for classifying paradoxical interventions have been offered in the literature (Rohrbaugh, Tennen, Press, & White, 1981; Seltzer, 1986). Of the many types, the most commonly used are symptom prescription and restraint from change. Variations of these two techniques—asking clients to engage in the behavior they wish to eliminate or restraining them from changing—have been applied in both individual and family therapy. However, nearly all controlled studies of therapeutic paradox have involved symptom prescriptions with individuals. Based on these studies, Shoham-Salomon and Rosenthal (1987, see below) reported that outcome largely depends on how these interventions are administered.

Most paradoxical interventions involve some combination of prescribing, reframing, and positioning. *Prescribing* means telling people what to do (giving tasks, suggestions, and so on) either directly or indirectly. For example, a therapist might ask a patient to have a panic attack deliberately or prescribe that an overinvolved grandmother take full responsibility for a misbehaving child, expecting that she will back off and let the mother take charge. *Reframing* involves redefining the meaning of events or behavior in a way that makes change more possible. Although reframing resembles interpretation, its goal is to provoke change rather than provide insight—and the accuracy of redefinition is less important than its impact. Thus, Haley described a case in which a wife became more sexually responsive after her frigidity was reframed as a way of pro-

tecting the husband from the full force of her sexuality, and Selvini-Palazzoli, Cecchin, Prata, and Boscolo (1978) pioneered the use of "positive connotation," a technique for changing dysfunctional family patterns by ascribing noble intentions to both the identified patient's symptom and the behaviors of family members that support it. *Positioning* is a term for altering the therapist's own role, or potential role, in a problem-maintaining system. Prescribing, reframing, and positioning are interwoven, with each at least implicit in any paradoxical strategy or intervention. Thus, prescribing that someone be deliberately anxious reframes an involuntary symptom as controllable; reframing problem behavior as a protective sacrifice carries an implicit (paradoxical) prescription not to change; and warning against dangers of improvement sometimes helps reverse or neutralize a therapist's role in a problem cycle.

Applications of paradox tend to be most varied and complex in marital and family therapy. In one case, where the focus was on reversing family members' well-intentioned but self-defeating attempt to solve a problem, a therapy team coached the relatives of a depressed stroke victim to encourage him by discouraging him (Fisch et al., 1982). In another case, a therapist asked a depressed husband to pretend to be depressed and asked his wife to try to find out if he was really feeling that way. For extreme marital stuckness, a therapist may recommend paradoxical interventions such as prescribing indecision about whether a couple should separate. The most dramatic examples of paradox with families come from the early work of the Milan team (Selvini-Palazzoli et al., 1978). After complimenting a severely obsessional young woman and her parents for protecting each other from the sadness associated with the death of a family member several years earlier, the team prescribed that the family meet each night to discuss their loss and suggested that the young woman behave symptomatically whenever her parents appeared distraught.

Clinical reports describe successful applications of paradoxical intervention with a wide variety of problems including anxiety, depression, phobia, insomnia, obsessive-compulsive disorder, headaches, asthma, encopresis, enuresis, blushing, tics, psychosomatic symptoms, procrastination, eating disorders, child and adolescent conduct problems, marital and family problems, pain, work and school problems, and psychotic behavior (Seltzer, 1986). Paradoxical strategies appear least applicable in situations of crisis or extreme instability, such as acute decompensation, grief reactions, domestic violence, suicide attempts, or loss of a job, but there have been too few controlled studies to list indications and contraindications with any degree of certainty.

While some authors advocate reserving paradoxical approaches for difficult situations where more straightforward methods have not succeeded or are unlikely to succeed, paradoxical strategies are too diverse for this to make sense as a blanket rule. For example, paradoxical symptom prescription could reasonably be a first line of approach for involuntary symptoms like insomnia that to some extent are maintained by attempts to stave them off.

Change Processes

Explanations of how and why paradoxical interventions work are as diverse as the interventions themselves. Behavioral, cognitive, and motivational processes—alone and in combination—have been proposed to explain change in both individuals and families. At the individual level, a behavioral account of why symptom prescription helps involuntary problems such as insomnia, anxiety, and obsessive thinking is that, by attempting to have the problem, a patient cannot continue in usual ways of trying to prevent it, thus breaking an exacerbation cycle. Cognitive explanations of the same phenomena emphasize that symptom prescription redefines the uncontrollable as controllable, decontextualizes the problem, and in a fundamental way alters the symptom's meaning. A third, rather different change mechanism has been suggested for situations where clients appear to defy or oppose a therapist's directive. Here the client presumably rebels to reduce psychological reactance, a hypothetical motive state aroused by threats to perceived behavioral freedom (Brehm & Brehm, 1981).

Not surprisingly, explanations of how paradoxical interventions promote change at the family-systems level are more diverse and more abstract. Some paradoxical interventions are assumed to interrupt problem-maintaining interaction cycles between people (Fisch et al., 1982), and some, like positive connotation, presumably operate by introducing information into the system or by changing the meaning of the symptom and the family interaction that supports it (Selvini-Palazzoli et al., 1978). Motivational explanations of systems-level change suggest that paradoxical interventions work by activating relational dynamics such as "compression" and "recoil" (Stanton, 1984) or by creating disequilibrium among systemic forces aligned for and against change (Hoffman, 1981).

Some theories of paradoxical intervention attempt to combine or integrate various change processes. For example, Rohrbaugh and colleagues (1981) proposed a compliance-defiance model distinguishing two types of paradoxical interventions. Compliance-based symptom prescription is indicated (a) when an "unfree" (involuntary) symptom like insomnia is maintained by attempts to stave it off, and (b) when the potential for reactance is low (i.e., when clients are unlikely to react against attempts to influence them). Defiance-based interventions, on the other hand, work because people change by rebelling. These are indicated when clients view the target behavior as relatively "free" (voluntary) and when the potential for reactance is high.

Another model of therapeutic paradox originally proposed by Watzlawick et al. (1967) incorporates behavioral and cognitive explanations of change. The therapeutic double-bind—a directive to deliberately engage in invol-

untary symptomatic behavior—is a mirror image of the pathogenic "be spontaneous" paradox. The only way to obey such a directive is by disobeying it. According to Watzlawick et al. (1967), two possible consequences follow: If the client is not able to produce the symptom on demand, he or she will show less of the problem; if the client does produce the symptom, it will be with a greater sense of mastery and control. In this way clients are "changed if they do and changed if they don't." If the symptomatic behavior itself does not change, at least the client's perception of it changes—and as Raskin and Klein put it, behaviors over which one has control might be sins, but they are not neurotic complaints. Studies by Shoham-Salomon and her colleagues provide empirical support for this "two paths to change" model.

Efficacy

When paradoxical interventions are part of a broader therapeutic strategy, their specific contribution to clinical outcome is difficult to evaluate. Nevertheless, dramatic and seemingly enduring effects on individuals and families have been documented in numerous clinical reports and case studies and in qualitative literature reviews (Seltzer, 1986).

Controlled experimental studies of paradoxical interventions with individual clients have yielded mixed results. Two independent meta-analytic reviews (Hill, 1987; Shoham-Salomon & Rosenthal, 1987) indicate that paradoxical interventions compared favorably to no-treatment control conditions, but comparisons to nonparadoxical treatments have been equivocal. Whereas Hill's (1987) meta-analysis found paradox to be superior, Shoham-Salomon and Rosenthal (1987) found that the overall effect of paradoxical interventions was as large (but no larger than) the average effect size of psychotherapy in general. Research also suggests that some forms of paradoxical intervention may be more effective than others. In Shoham-Salomon and Rosenthal's (1987) meta-analysis, the effect sizes of two positively connoted symptom prescriptions were significantly greater than those of other, nonparadoxical treatments or of symptom prescriptions that did not include a positive frame. Paradoxical interventions were most effective when the therapist either reframed the symptom positively before prescribing it (for example, praising a depressed client's tolerance for solitude or her willingness to sacrifice for the good of others), or explained the paradoxical intention (exacerbation-cycle) rationale in a way that defined the client as not "sick" but "stuck." In a recent study directly testing the importance of positive connotation, Akillas and Efran found that socially anxious men improved more when a prescription to be anxious was presented with a positive frame (rationale) than when it was not. This supports the view that symptom prescriptions work best when they aim to alter the meaning a client attributes to the symptom.

Research on paradoxical interventions is not without limitations. For example, meta-analytic results must be interpreted cautiously because stringent inclusion criteria may compromise the clinical or ecological validity of conclusions. Moreover, as noted above, research in this area has focused almost exclusively on symptom prescription with individuals. There have been too few controlled studies to summarize the efficacy of other forms of therapeutic paradox (restraint from change, for example) or of applications with interactional systems and families.

Ethical Issues

As the popularity of paradoxical therapy increased during the 1980s, concern also grew about ways in which these techniques can be misused. Strategic applications in which therapists do not make their rationale for particular interventions explicit to clients have been criticized as manipulative and potentially harmful to the client–therapist relationship. And in analogue studies, observers of therapy vignettes have rated symptom prescription as less acceptable than straightforward behavioral interventions, even when these vignettes portrayed paradoxical interventions as more effective.

Defenders of strategic therapy, on the other hand, argue that good therapy is inherently manipulative and that therapeutic truth-telling can be not only naive but discourteous. Responsible therapists of all persuasions agree that paradox should not be used for the shock value or power it promises. Encouraging a symptom or restraining people from changing can be disastrous if done sarcastically or from a sense of frustration ("There's the window—go ahead and jump!"). It is also significant that therapists like Haley, Weakland, Palazzoli, and Hoffman, who pioneered the use of paradoxical methods, now give them less emphasis; even therapists well-versed in strategic methods find the term "paradoxical" confusing, inaccurate, and overly loaded with negative connotations. Of particular concern is that the term "paradoxical intervention," cut loose from its theoretical and clinical moorings, is too easily seen as a "quick fix" or a gimmick.

Three guidelines may decrease the potential for misusing paradoxical interventions: First, define behavior positively. When prescribing a symptom or restraining change, avoid attributing unseemly motives to people (like needing to control, resist, or defeat one another); ascribe noble intentions not only to the symptom but to what other people are doing to support it. Second, be especially cautious with challenging or provocative interventions. When restraining clients from change, for example, it is safer to suggest that change may not be advisable than to predict it will not be possible. Finally, have a clear theoretical formulation of how the problem is being maintained and how a paradoxical intervention may help to change that. The most important guideline for paradoxical (or any other) intervention is having a coherent rationale for using it.

PARADOXICAL SLEEP

Paradoxical sleep is a sleep stage characterized physiologically by a lack of muscle tone, rapid eye movements (REMs), and an awake cortical electroencephalographic (EEG) pattern. The “paradox” refers to the disparity between the alert EEG pattern, implying that the person is awake or nearly so, and the indications that the person is actually more deeply asleep than at other times (difficulty in arousing, reduced muscle tone).

The term *paradoxical sleep* was introduced in a 1967 *Scientific American* article on the states of sleep by French researcher Michel Jouvet. Jouvet used the term to describe a period of apparent sleep in cats in which they exhibited high levels of neural activity with completely relaxed neck muscles. In humans, such periods are also characterized by rapid eye movements; sleep researchers use the term *REM sleep* with human subjects but *paradoxical sleep* with animals because many species do not exhibit eye movements.

REM or paradoxical sleep is just one of several stages that a sleeping organism passes through during a sleep bout. One way to categorize the stages is into REM sleep and non-REM (NREM) sleep. Four stages are usually distinguished in NREM sleep, labeled appropriately Stages 1–4, with the stages representing progressively deeper sleep. Stages 3 and 4 are collectively called *slow-wave sleep* (SWS) because the EEG waves are slower than in Stages 1 and 2.

REM sleep is associated with erections in males and vaginal moistening in females, as well as with reports of dreaming. In males at least, the genital changes are not necessarily associated with sex-related dreaming. Dreams also have been reported in SWS, but they are more frequent in REM sleep and generally more elaborate.

Studies of people awakened from REM sleep have answered several questions about dreaming. For example, apparently all normal humans dream, even though many people claim that they do not. When “nondreamers” are awakened during REM sleep, they usually report dreams, although their dreams may be less vivid than those of people who usually remember their dreams upon awakening. Another observation is that dreams last about as long as they seem to.

A number of studies have attempted to determine the function of REM sleep by depriving volunteers of it. In general, subjects awakened during each REM stage and kept awake for several minutes increase their attempts at REM sleep and develop mild, temporary personality changes. Studies of paradoxical sleep deprivation in animals reveal similar increased attempts at REM sleep and some general disturbances, none of which solves the mystery of REM sleep’s function.

According to one explanation, sleep is an adaptive mechanism developed to conserve energy at night, when food gathering would be difficult for an animal active in the daytime. However, the evolution of many animals has resulted in regular patterns of locomotor activity, thought to

occur approximately every 2 hours, during which food gathering and other activities related to survival might occur. If this 2-hour cycle continued around the clock, the animal would have its sleep periodically interrupted. Thus, in order to get a full night's sleep and continue with the 2-hour activity cycle, the animal enters a period of paradoxical sleep in which only the brain awakens.

Another possibility is that REM or paradoxical sleep is important for strengthening memories. Studies have shown that humans and other mammals increase REM sleep periods following a new learning experience, and without this increase, memory deficits result. However, some have suggested that REM sleep performs just the opposite function: purging useless information from memory. Yet another possibility is that infants spend an inordinate amount of time in REM sleep because such sleep is associated with the development of the brain. About all we can say at this time is that the number of disparate explanations indicates that we really do not know much about the causes and functions of paradoxical sleep.

PARAMETRIC STATISTICAL TESTS

Parametric statistical tests, as opposed to nonparametric or distribution-free tests, are based on various assumptions regarding the characteristics, properties, and form of the distributions of populations from which the data are drawn. A large number of statistical tests are included among the parametric tests, primarily hypothesis-testing procedures derived from the general linear model. These include both univariate and multivariate statistical tests: the *t*-test, univariate and multivariate analysis of variance and covariance (including repeated measures), Pearson product-moment correlation, simple and multiple regression (and variants including logistic regression), Hotelling's T^2, discriminant function analysis, canonical correlation, and multivariate set correlation. When their underlying assumptions are met, parametric statistical tests are generally considered more powerful than their nonparametric alternatives. However, it is more for their versatility than for their statistical power that parametric tests have become the most common tools in behavioral research.

The principal assumptions on which parametric tests are based include independence of the observations, normality of the underlying distributions, homogeneity of variance across groups (for multiple group procedures), continuity of measurement, and equality of intervals of measurement. Additional assumptions may be required for some parametric procedures, such as linearity of regression (Pearson correlation, simple and multiple regression), homogeneity of regression slopes (univariate and multivariate analysis of covariance), and sphericity (univariate and multivariate repeated measures). The principal assumptions for multivariate statistics include independence of the observations, multivariate normal distributions for all dependent variables, and homogeneity of the variance–covariance (dispersion) matrices across groups.

In principle, when assumptions are violated, the significance level (*p* value) associated with a statistical test result may be seriously in error, increasing either Type I or Type II error rates. However, under many circumstances, univariate statistics seem to be quite robust to violations of assumptions. One exception is the violation of the assumption of independence, which is always serious. Robustness may also be compromised under certain conditions, such as when two or more assumptions are violated simultaneously, when sample sizes are very small, when sample sizes are unequal, or when one-tailed significance tests are used. When violation of assumptions is a concern, various remedial techniques can be employed, including data transformations (e.g., square root, arcsine, log) or the use of alternative, specialized analytical procedures (e.g., Welch's *t*-test, generalized estimating equations, nonparametric statistics). The assumptions underlying repeated measures procedures appear to be more restrictive than for univariate tests. Consequently, repeated measures procedures may not be as robust as univariate tests. Although not as much research has been conducted as for univariate procedures, multivariate statistical tests appear to be robust to violation of assumptions under many commonly occurring circumstances.

PARASYMPATHETIC NERVOUS SYSTEM

The *parasympathetic nervous system* (PNS) is one of two branches of the autonomic nervous system, which controls the function of organs and glands in the body (called the efferent portion) and senses changes in these organ systems (the afferent portion). The other autonomic branch is called the *sympathetic nervous system* (SNS). The neurons that comprise the efferent PNS arise from either the cranial nerves that exit from the brain stem and spinal cord, or from the sacral (i.e., lower) portion of the spinal cord. Thus, this system is sometimes referred to as the craniosacral branch. Cranial parasympathetic fibers innervate the organs and glands of the head, neck, chest, and upper abdomen, including the upper portions of the gastrointestinal (GI) tract. The sacral parasympathetic fibers innervate the lower GI tract and other organs of the pelvis.

The anatomy of the efferent autonomic nerves to each organ or gland includes preganglionic neurons, which exit the brain or spinal cord, and postganglionic neurons, which directly innervate the target organ. A ganglion is comprised of the cell bodies of the postganglionic neurons and is the region where the pre- and postganglionic neurons communicate with one another. In the PNS, the preganglionic fibers exiting the brain or spinal cord extend across relatively long distances in the body before reaching the ganglion. Typically, PNS ganglia are found very near or even in the wall of the target organ or gland. Thus, the postganglionic neurons are very short, since they extend only from the ganglion to the target organ. The neurotransmitter released by the axon terminals of the preganglionic neurons is acetylcholine. Acetylcholine acts on cholinergic receptors of the nicotinic subtype, which are found on the postganglionic neurons. The neurotransmitter released by the postganglionic neuron onto the target organ or gland is acetylcholine, which activates muscarinic subtype cholinergic receptors. Afferent autonomic fibers from organs to the central nervous system run alongside the same nerves carrying efferent autonomic fibers. The visceral (i.e., organ) afferents comprise a relatively large proportion of the total number of fibers, perhaps 50% or more, in the parasympathetic nerves. Afferent autonomic fibers provide sensory information about the state of an organ, such as stretch of the bladder, and also may relay some pain signals.

The organs and glands controlled by the efferent PNS typically receive input from both branches of the autonomic nervous system, a phenomenon referred to as dual innervation. When organs receive innervation from both autonomic branches, activation in the two branches often, but not always, produces opposite effects on the organ. For example, the heart rate is controlled by both autonomic branches. Increased activity in the parasympathetic branch decreases heart rate, and decreased activity increases heart rate. Conversely, increased activity in the sympathetic branch increases heart rate, whereas decreased activity decreases heart rate. Thus, each of the two branches is capable of bidirectionally influencing the rate at which the heart beats.

When the body is at rest, many of the organs of the body are conserving or actively storing metabolic resources for later use, a process known as anabolism. Often during such states, activity in the parasympathetic system is relatively high compared to periods when the organism is moving, challenged, or distressed. For example, during rest or low levels of bodily activity, digestion of food is a priority for the body. Increased parasympathetic activation enhances digestion by producing increased motility and blood flow, and the secretion of digestive fluids such as acid and enzymes into the gastrointestinal tract. When an organism requires metabolic energy to maintain activity above resting levels, for example in response to a stressor or with physical exertion, activation of the parasympathetic system tends to decrease at the same time that activation of the sympathetic system tends to increase. At very high levels of metabolic need, parasympathetic activation of some organs may cease altogether. Most of the time, the autonomic nervous system operates somewhere between these extremes of low and high energy mobilization. In these cases, PNS effects on the organs and glands will be intermediate and tuned to the specific needs of each organ system.

In addition to the tendency for the two autonomic branches to operate in a reciprocal fashion under extremes of activity or inactivity, the two autonomic branches can operate nonreciprocally and independently. Thus, although a typical pattern of autonomic control consists of the activation of one autonomic branch accompanied by a decrease in activity in the other branch (a reciprocal pattern), this is not the only pattern of response that can occur. The two autonomic branches can have uncoupled effects on an organ with either increased or decreased activity in one autonomic branch in the absence of any change in activity in the other branch. Alternatively, the two branches can exert coactivational effects where there are simultaneous increases or decreases in activity in both autonomic branches. The existence of the nonreciprocal patterns means that one cannot measure function in one autonomic branch and on that basis alone infer the activation level in the other branch.

PARENT MANAGEMENT TRAINING

Parent management training (PMT) employs a therapist as a consultant who works directly with a parent (mediator) to alleviate the problem behavior of a child (target). The basic PMT format consists primarily of instruction by the therapist in parenting techniques, structured modeling, role-plays and practice sessions, and homework assignments for the parent to practice skills with the child. This format is based on the assumption that parenting skills deficits are at least partly responsible for the development

and/or maintenance of child problem behaviors, and thus provides parents with a repertoire of skills with which to manage, and eventually improve, the child's behavior as well as improve broader parent-child interactional patterns.

PMT has been utilized as a therapeutic intervention primarily for disruptive or "acting-out" behavior (e.g., aggression, noncompliance, destructiveness) of children. This type of behavior is one of the most frequent causes of referrals for child mental health treatment. Disruptive, aggressive, or delinquent behavior of children and adolescents is a significant problem for society, not only as a direct result of the difficulties caused by such behaviors themselves, but also because such behavioral patterns often persist, or worsen, into adulthood, when their consequences are much greater.

Because the emotional and financial costs associated with disruptive behaviors can be so significant for families and society, clinical researchers have devoted substantial energy to understanding the causes of this behavior and determining ways of treating and preventing it in youth. Countless studies have shown that the family is one of the most consistent areas of a child's life that contributes to both the development and the treatment of disruptive behavior. Positive parenting practices, such as a supportive parent-child relationship, authoritative discipline methods, and close supervision are major protective factors against the development of disruptive behavior. In contrast, negative or coercive parenting practices, such as harsh punishment, psychological control, and negative parent-child interactions contribute to the development of child and adolescent problem behavior. As such, PMT, which targets these areas of parenting, has become the intervention of choice for treating and preventing disruptive behavior problems of children and adolescents. Empirical studies, meta-analyses, reviews, and task force conclusions all provide substantial support for PMT as one of the most effective therapeutic interventions for the disruptive or acting-out behavior of children.

The development of PMT as an empirically validated practice has occurred in three distinct stages: establishment, generalization, and enhancement. The first stage (from 1960 to 1975) involved the establishment of the parent training format and tests of its efficacy as a treatment for child problem behaviors. Early studies, which included a large number of descriptive studies and single-case designs, found support for the short-term efficacy of the parent training model in reducing disruptive child behaviors and improving parenting practices.

The second stage of research was conducted between 1975 and 1985 and focused on the long-term effects and generalization of PMT. Such generalization has been shown to occur in at least four areas: setting (e.g., transfer of behavior changes from the clinic to home or school), temporal (e.g., maintenance of behavior change over time), sibling (e.g., application of new parenting skills with non-targeted children), and behavioral (e.g., concomitant improvements in non-targeted behaviors). The empirical demonstration of the generalization of treatment effects has served to enhance the perceived social validity of parent training (i.e., whether the treatment effects are considered to be clinically or socially important to the client as well as the clients' satisfaction with the treatment).

The third stage of PMT research, which began in 1986 and continues today, examines ways to expand and enhance the PMT curriculum. This line of research has considered a wide range of factors that can impact the implementation and outcome of parent training. For example, the role of developmental variables (e.g., the child's age) has been emphasized in developing and tailoring PMT interventions. As a child increases in age, her or his cognitive abilities and source of primary reinforcement (e.g., parents, peers) change, which leads to changes in intervention strategies. PMT has been found to be more effective with younger than older children, and the families of younger children are less likely to drop out of treatment. With older children, particularly adolescents, PMT interventions may not only be less effective but also more difficult to implement. As another example of the findings from this stage of PMT research, several researchers have considered the contextual factors that can affect PMT, thus broadening the perspectives for treating child disruptive behavior. For example, in addition to the traditional teaching of parenting skills, the PMT paradigm may be modified to include multiple areas of family functioning as targets for intervention (e.g., parental depressive symptoms and/or marital adjustment). More recently, interventions have been designed to involve and coordinate multiple levels of the child's environment, including the home, school, clinic, and community.

PMT programs all share several common or core elements, including: (1) focusing more on parents than on the child; (2) teaching parents to identify, define, and record child behavior; (3) instructing parents in social learning principles (e.g., reinforcement of prosocial behavior, withdrawal of attention for misbehavior through the use of ignoring or time-out); (4) teaching new parenting skills via didactic instruction, modeling, role-playing, and practicing with the child in the clinic and at home; (5) discussing ways to maximize generalization of skills from the clinic to the home; and, when necessary, (6) addressing contextual issues affecting parents (e.g., depressive symptoms), the family (e.g., marital conflict), and the community (e.g., neighborhood violence) which may interfere with the acquisition or maintenance of new parenting skills and the promotion of adaptive child behavior.

PARENTAL APPROACHES

Parents have a legal and moral duty to rear their children. This includes providing for their sustenance and well-being, as well as their social, ethical, and personal development. In order to fulfill this responsibility, parents have to find ways to convey their principles, expectations, and regulations. Thus, the goal of parenting is to raise confident and satisfied children who can function independently and contribute to the welfare of society.

Historically, children were considered property of the father. Fathers had the supreme right to command blind obedience. In addition, religious doctrine mandated that parents make their children god-fearing subjects by requiring them to submit to religious commandments, "to honor thy mother and father." Thus, an authoritarian style of parenting was purported to be the optimal method for transferring the philosophy and practices of the parents to the children.

In the 1900s, psychoanalytic premises stressed attention to children's instinctive needs. Autocratic child rearing practices were seen as contributing to the anxiety of children by precipitously and abruptly addressing their psychosexual developmental needs. Instead, a philosophy of parental permissiveness was seen as the optimal method in order to follow the wisdom of the unconscious. Thus, parents were encouraged to indulge children by practicing a "laissez-faire," nonintrusive approach with their children.

Dreikurs and Grey (1968), students of Alfred Adler, adopted a democratic position of parenting that forged a middle ground of parental authority. They stressed that children should be encouraged to balance freedom with responsibility. The combination of teaching children both freedom and responsibility added new challenges to the task of parenting. Parents no longer had an either/or solution of tyranny or indulgence, but needed to creatively encourage children through natural and logical consequences.

Benefits of Authoritative Parenting

Diana Baumrind's research of more than 30 years supported the benefits of a rational approach to parenting that fostered child development through an artful balance of control and responsiveness. Baumrind (1967, 1971) initially articulated three parental styles of handling authority as *authoritative, authoritarian,* and *permissive.* Later, she added a fourth category called rejecting–neglecting, or parents who were *unengaged.*

In cluster and factor analyses, Baumrind (1989) identified *demandingness* and *responsiveness* as the two major modalities in the parenting process. Demandingness correlates with parental attributes that provide appropriate direction and control. Demanding parents can be *confrontive* even if such a position results in open conflict. Confrontation is contrasted with coercive approaches that demand power without reason. Confrontation of the problem behavior (versus intimidating the child) can result in resolution and negotiation of conflict, which enhances the child's internal decision making, self-esteem, and communication skills. Parents who insist that children embrace individually appropriate levels of responsibility, those who make *high maturity demands,* promote higher levels of prosocial behavior and academic competence. Appropriate parental *monitoring* is preferable to an overly intrusive and constrictive approach, which diminishes an appropriate level of exploration and autonomy. Reinforcement, logical consequences, and rational punishment are methods that can teach children desirable values, attitudes, and behaviors.

Table 1. Parental Styles

	Responsiveness	
Demandingness	High	Low
High	Authoritative	Authoritarian
Low	Permissive	Unengaged

The preceding attributes of parental authority, alone, are insufficient to raise healthy, confident, and competent children. Parents who demonstrate *responsiveness* establish a loving environment that is sensitive to and accommodative of the child's needs (Bowlby, 1969). Children who experience *affective warmth* from a parent develop feelings of object permanence and feel securely *attached and bonded* to their environment. These children become attuned to the demands of the parent and are more likely to be cooperative than children with a cold or uninvolved parent. *Reciprocity* is the extent to which parents listen and respond to the needs and feelings of the child. Parents *sensitively attuned* to the child's motivational system can use reciprocity to uncover "win-win" solutions in the intergenerational dialogue. Parents who are responsive model prosocial communications to the child and produce children who authentically desire harmony with their parents.

Authoritative parents, who are high in both responsiveness and demandingness, remain receptive to the needs of the child for attachment and autonomy, but take responsibility for firmly guiding the actions of the child. Authoritarian (autocratic) parents are high in demandingness but low in responsiveness. They set absolute standards for their children and require unquestioned obedience and submission to their authority. Permissive (indulgent) parents are high in indulgence but low in control. These parents put few demands on their children, usually accept their children's impulses, and for the most part, avoid conflict. Unengaged (neglectful-rejecting) parents are low in both authority and nurture. Out of all parental styles, they produce children with the most severe problems because their children are forced to fend for themselves or depend too greatly on their peer group for support.

Cultural Considerations

Baumrind's early research (1967, 1971) began by measuring mostly middle-class, Caucasian children who were being raised by one or both parents. Nonetheless, much of the research holds that authoritative parenting works best across differences of culture, race, gender, socioeconomic factors, and family structure. Therefore, authoritative caregiving can be effective for child rearing regardless of the relationship between caregiver and child. However, Baumrind (1995) cautioned that the blend of demandingness and responsiveness is dependent upon the social and cultural context of the child.

Brofenbrenner (1979/1982) agreed that the optimal balance of freedom and control depends upon the level of stability of the larger society. Due to the massive change of the family's ecology, he suggested that there is a greater need for structure in the modern family. More specifically, Kohn (1977) stated that African American parents often used authoritarian methods to instill obedience and authority in their children to help them adapt to a bicultural reality of minority status in the American culture. Thus, parenting does not occur in isolation of the context.

Similarly, there have been different gender implications of parenting styles. The authoritarian approach emanates from a masculine manner of handling authority, whereas authoritative parenting is much more compatible with female development and feminine use of authority. Gilligan's (1982) research proved that girls respond much more to a consensually-based approach so that they can discover their own voice.

Summary

Research on parental approaches strongly supports an authoritative approach, which blends a flexible balance of demandingness and responsiveness through the child's developmental process. This approach provides the nurture, safety, protection, respect, and responsive limits (Pesso, 1973) that children need to optimize their potential as healthy, confident, and vital members of society. However, parents need to adapt the mixture of demandingness and responsiveness to the idiosyncrasies of the child, culture, and context.

PARTNER ABUSE

Partner abuse, often referred to as intimate partner violence, partner aggression, domestic violence, or spouse abuse, is a very broad term encompassing three diverse categories of abusive behaviors that occur within the context of intimate relationships: physical, sexual, and psychological. Partner physical abuse includes behaviors ranging in severity from those that are unlikely to result in injury (e.g., pushing and grabbing) to those that are life threatening (e.g., choking, kicking, and beating up). Partner sexual abuse refers to any undesired sexual contact that is psychologically or physically coerced. The definition of partner psychological abuse is particularly broad, encompassing behaviors ranging from insulting or swearing at a partner, to threatening a partner, to engaging in jealous behaviors, to isolating a partner from friends and family. In most cases, particularly when the aggression is mild to moderate, partner abuse is bilateral. That is, both partners engage in aggressive or abusive behaviors. However, in our clinical and research experience, in relationships in which women are severely abused and often injured, men are much more likely to be abusers than are women, and women's aggression is often in self-defense (see also Johnson, 1995). Female victims of such severe partner abuse are often referred to as battered women, and their abusive partners are often referred to as batterers.

Given the greater research emphasis on physical abuse as compared with psychological and sexual abuse in intimate relationships, partner physical abuse is the main focus herein.

Prevalence

Partner physical abuse is a relatively common form of violence in our society. The 1975 and 1985 National Family Vi-

olence Surveys revealed that each year approximately 12% of married or cohabiting men and women in the United States engage in physical aggression against a partner, and approximately 3 to 5% engage in severe or life-threatening physically assaultive behaviors against a partner (Straus & Gelles, 1990). Partner abuse is not limited to adult heterosexual married and cohabiting relationships, but also occurs in a substantial number of adolescent dating relationships (Halpern, Oslak, Young, Martin, & Kupper, 2001) and same-sex romantic relationships (Renzetti & Miley, 1996). Although the statistics presented above only reflect the prevalence of partner abuse in the United States, partner abuse is currently recognized as an important problem throughout the world (Walker, 1999).

Explanatory Frameworks and Risk Factors

Several explanatory frameworks have been developed to describe the causes of partner abuse. Feminist accounts identify partner abuse as a product of a patriarchal (male-dominated) society. Violence in the home is viewed as one of many expressions of gender-based power inequality in society (Yllö, 1993). Psychological accounts identify partner abuse, particularly severe partner abuse, as a manifestation of the interaction between individual personality traits or personality disorders and other risk factors such as marital dissatisfaction (O'Leary, 1993). Sociological accounts identify position in the social structure as an important causal factor in partner abuse. Substantial research linking variables associated with position in the social structure, such as poverty, age, and race, to partner abuse provides support for this explanatory framework (Gelles, 1993). Numerous other social, psychological, and biological factors, such as anger, depression, witnessing violence as a child, relationship communication problems, and alcohol problems are associated with increased risk for partner abuse perpetration, and may be causally related to such abuse (Schumacher, Feldbau-Kohn, Slep, & Heyman, 2001).

Consequences

As a result of partner abuse, society incurs substantial costs related to physical and mental health care, legal interventions, child welfare, social services, and lost work productivity. At the individual level, partner abuse can have very negative effects, particularly for women. Although women engage in physically aggressive behaviors against a partner at approximately the same rate as men, the findings of the National Violence Against Women Survey indicate that women are significantly more likely to sustain injuries, receive medical care or be hospitalized, receive counseling, and lose time at work as a result of partner abuse victimization than are men (Tjaden & Thoennes, 2000). Violence by a partner is also a surprisingly common cause of death for young women, claiming roughly 2,000 lives annually (Browne & Williams, 1993). Partner abuse has also been associated with negative consequences for individuals who witness the violence as children. The results of a survey of more than 17,000 adult HMO members in California indicated that adults who reported having been raised in environments in which partner abuse occurred were significantly more likely to also report other adverse experiences during childhood, such as child abuse and neglect, than adults who were not raised in such environments. Further, the frequency of witnessing partner abuse as a child was related to self-reported alcoholism, drug use, and feelings of depression in adulthood (Dube, Anda, Felitti, Edwards, & Williamson, 2002).

Intervention and Prevention Strategies

A variety of psychological interventions are currently utilized, particularly psychoeducational and therapy groups for men (and occasionally women) who abuse their partners. Various legal interventions including arrest, prosecution, and restraining orders are also used to manage this problem. For severely abused women, support groups are commonly used along with legal advocates, shelters, social service agencies, and individual therapeutic interventions to help victims leave abusive relationships and rebuild their lives. For women and men in less severely abusive relationships where both the male and female engage in physically aggressive behaviors, couple or marital therapy based interventions designed specifically to reduce psychological and physical aggression can be useful (O'Leary, Heyman, & Neidig, 1999). Dating violence prevention programs in junior high and high school are designed to provide children with education and skills and to foster attitudes that will reduce or prevent partner abuse in their current and future relationships. Partner abuse is clearly a multidetermined problem that is influenced by a variety of psychological and social factors. As a result, this problem requires multifaceted interventions including legal, psychological, social, and medical approaches.

PASTORAL COUNSELING

Pastoral counseling is a modern and psychologically sophisticated form of religious caring. Usually offered by a minister, priest, rabbi, chaplain, or other religious worker, pastoral counseling seeks to combine skilled counseling methods with an understanding and application of the moral guidelines and spiritual values of religion.

In contrast to the term *religious counseling,* which is not limited to Christian pastors or to Western systems of belief, the term *pastoral counseling* usually is limited to the help given by religious leaders whose beliefs are based in Judaic/Christian traditions.

The Bible is filled with examples of dedicated men and women who encouraged, guided, supported, confronted, comforted, advised, and in other ways helped people in need. Throughout the Christian era, pastors and other religious workers have engaged in what have come to be known as the four pastoral functions: (a) healing (restoring individuals to wholeness and leading them to advance beyond their previous conditions); (b) sustaining (helping hurting people to endure and to rise above difficult circumstances); (c) guiding (assisting perplexed individuals as they face difficult decisions); and (d) reconciling (reestablishing relationships between people and between individuals and God).

The modern pastoral counseling movement began in the 1920s as a reaction against both traditional theological education, which tended to have little practical and pastoral emphasis, and early psychiatric treatment, which had little place for religious perspectives on healing.

Clinical Pastoral Education (CPE) has developed into a highly organized movement. Much of its work has been in providing standards and guidelines for the training of pastoral counselors; demonstrating to both hospital personnel and theological educators that pastoral involvement is relevant and effective in the treatment of psychological and physical illness; investigating ways in which theology and the psychological sciences can be related; and showing that the personal and spiritual development of seminarians is at least as important as intellectual training for the ministry.

Pastoral counselors of all theological persuasions deal with personal, social, marital, family, and religious problems. Much of the emphasis in pastoral counseling is on coping with present problems, helping those who suffer, and giving spiritual guidance.

Pastoral counseling takes place not only in pastors' offices and church settings but also in hospital rooms, prison cells, parishioners' homes, restaurants, military settings, and funeral homes. Hospital and military chaplains usually identify themselves as pastoral counselors, as do college chaplains and chaplains associated with major league sports teams.

As pastoral counseling has become more popular and its effectiveness more recognized, increasing numbers of pastors are finding themselves swamped with requests for counseling. To meet these needs, several trends have become apparent within the pastoral counseling movement. These include increased communication and cooperation among pastors and professionals in the helping fields; the development of better training programs in seminaries; the stimulation of lay counseling within and through the local congregation; the establishment of pastoral counseling centers; the involvement of pastors in new and established counseling clinics and community centers; the consideration of ways in which problem prevention can be stimulated by and through the church or synagogue; the increased use of sermons and small study groups as ways of stimulating mental and spiritual health; and the development of films, seminars, and training programs that can supplement, replace, and prevent the need for counseling.

PATIENT ADHERENCE

Adherence

Adherence is defined as the extent to which patients follow prescribed regimens (Haynes, Taylor, & Sackett, 1979). Adherence to prescribed treatment regimens supports health promotion (e.g., exercise and diet), treatment of disease, symptom management, and efficient health care delivery. The term *adherence* is used rather than *compliance* because its meaning is more consistent with views of patients as active participants in health care rather than passive recipients of services (e.g., O'Brien, Petrie, & Raeburn, 1992). While this article is limited to medication adherence, the issues are relevant for adherence to other prescribed regimens.

Adherence involves a complex set of behaviors. It requires that patients take a medication at the prescribed time, in the correct amount, using indicated conditions (e.g., with meals). Since adherence failures involve errors of omission, commission, or timing, reported adherence rates need to be defined. Patients are sometimes classified as nonadherent if they are less than 100% adherent, but an 80% level is considered acceptable (O'Brien et al., 1992). Ideal adherence is dependent on the specific medication, treatment goals, and individual factors including age, disease severity, and health-related quality of life.

Measurement

Adherence measures should be unobtrusive, objective, and practical (Rudd, 1979). Biological measures (e.g., blood assays) can be obtrusive, whereas microelectronic monitoring is relatively unobtrusive and objective (Park & Jones, 1997). Although practical, self-reports of adherence and pill counts have been shown to overestimate adherence to medications and therefore are a less desirable method of measuring adherence (Guerrero, Rudd, Bryant-Kosling, & Middleton, 1993; Lee et al., 1996).

Extent and Consequences of Nonadherence

Estimates of nonadherence range from 30 to 60% for a variety of patients, diagnoses, and treatments (e.g., Rogers & Bullman, 1995; Haynes et al., 2002). Nonadherence to medication reduces health outcomes by lowering drug efficacy and producing drug-related illness due to incorrect doses or drug combinations (e.g., Col, Fanale, & Kronholm, 1990). Because adherence is often not monitored (Steele, Jackson, & Gutman, 1990), inadequate assessment of treatment efficacy can occur (Dunbar-Jacob, Burke, & Puczynski, 1995).

Theories of Nonadherence

Social-behavioral theories used to explain nonadherence include the Health Belief Model (Strecher & Rosenstock, 1997), Common Sense Model (Leventhal, Leventhal, Robitaile, & Brownlee, 1999), and Social Learning Theory (Bandura, 1997). Park and colleagues (Park et al., 1999) integrate psychosocial approaches with cognitive theory. They propose that nonadherence is influenced by illness representation, cognitive function, and external aids. Multifactor models recognize that patients must understand how to adhere, accept the prescribed regimen, develop an adherence plan that integrates information for all medications, and then implement the plan (Morrow & Leirer, 1999).

Predictors of Nonadherence

Nonadherence occurs for many reasons: Patients may nonadhere intentionally to avoid side effects (Cooper, Love, & Raffoul, 1982), unintentionally because of barriers (e.g., affordability), or inadvertently because they do not understand or remember how to take the medication.

Illness and Treatment Variables

Nonadherence increases with regimen complexity (e.g., times of day) (Ascione, 1994) and varies with symptoms (O'Brien et al., 1992), medication side effects (Haynes et al., 1979), illness representation (Leventhal & Leventhal, 1999), perceived benefits of treatment, and severity of illness (Strecher & Rosenstock, 1997).

Patient Variables

There is little evidence that nonadherence varies with gender, socioeconomic, or ethnic factors (Dunbar-Jacob et al., 1995). Nonadherence is associated with education, cognitive ability, and age. Less educated patients tend to have lower health literacy (ability to understand basic medical and services information), leading to poor health outcomes and lower utilization of services (Gazmararian et al., 1999). Older adults' nonadherence is a critical problem because they are a growing segment of the population, tend to use more health services, and are vulnerable to the consequences of nonadherence (e.g., Ascione, 1994). Older adults' comprehension of medication information is predicted by education level (Diehl, Willis, & Schaie, 1995) and nonadherence by cognitive decline (Morrell et al., 1997; Park et al., 1992). However, nonadherence may be higher for middle-aged than for young-old adults (ages 65–74; Morrell et al., 1997; Park et al., 1999), perhaps because busy lifestyles increase forgetting.

Provider-Patient Communication

Patient adherence also relates to improved physician communication variables, such as amount of information and partnership building (Hall, Roter, & Katz, 1988).

Reducing Noncompliance

There are few intervention studies with rigorous designs such as randomized control trials (Haynes, McKibbon, & Kanani, 1996; Roter et al., 1998; Haynes et al., 2001). Moreover, interventions targeting adherence alone are not sufficient because the goal is to improve clinical outcomes (e.g., Haynes et al., 2001).

The literature suggests the importance of several interventions, although they tend to be complex and difficult to implement. More convenient care, improved instruction, reminders, self-monitoring, reinforcement, counseling, family therapy, attention, and tailoring the regimen to daily habits are among successful approaches (Haynes et al., 2002). Interventions often involve cognitive or psychosocial approaches.

Cognitive Approaches

Nonadherence is associated with more complex regimens, suggesting that simplifying regimens by reducing or synchronizing times improves adherence (Ley, 1997; Baird et al., 1984). Sensorimotor barriers can be mitigated by simple interventions such as large print on labels and easy-to-open containers (Ascione, 1994). Comprehension and memory problems are addressed by improving instructions, including providing more information and using simple language, clear formats, and organization based on patients' schemas for taking medication (Hartley, 1999; Morrow et al., 1988; Morrow & Leirer, 1999). Pictures in instructions address problems related to limited education and literacy (e.g., Morrow & Leirer, 1999). Nonadherence is reduced by improved packaging (e.g., Wong & Norman, 1987), calendars or other aids that help patients organize (e.g., MacDonald, MacDonald, & Phoenix, 1977), pill organizers if they are correctly loaded (Park & Jones, 1997), and automated telephone messages that support prospective memory and symptom monitoring (e.g., Tanke & Leirer, 1994).

Psychosocial Approaches and Patient Education

Educational programs based on psychosocial approaches focus on intentional nonadherence. There is evidence that they improve adherence by targeting belief-based barriers such as perceived vulnerability to illness and benefits and costs of treatment (Janz & Becker, 1984; Strecher & Rosenstock, 1997). Benefits may occur for reasons in addition to influencing specific beliefs, such as increased patient knowledge (e.g., Brown, 1990) or self-efficacy (e.g., Lorig et al., 1989).

Other Interventions

Several methods attempt to shape adherence behavior, including behavioral contracting (Haynes et al., 1979), feedback (Kruse, Rampmaier, Ullrich, & Weber, 1994), and financial incentives (Giuffrida & Torgerson, 1997). Nonadherence is reduced by increasing social support, which may reflect the influence of significant others on patients' prospective memory, health beliefs, or self-efficacy (Park & Jones, 1997).

Conclusions

Although there are many adherence studies, few have adequately measured adherence, and nonadherence remains a pervasive health care problem (e.g., Haynes et al., 2001). Challenges for future research include the following: There is a need for intervention research based on comprehensive models that address both intentional and unintentional adherence (see Park & Jones, 1997). A complex, patient-based approach is needed, including profiles of nonadherent patients so providers can recommend methods for specific nonadherence conditions. Finally, research should focus on implementing interventions within existing health delivery systems once efficacy has been demonstrated in clinical trials.

PEER COUNSELING

Peer counseling is defined as the performance of limited counselor functions, under counselor supervision, by a person of approximately the same age as the counselee. The

majority of peer counseling programs are conducted at the college level, although secondary and elementary schools are also involved. Community mental health agencies and penal systems have developed paraprofessional models using indigenous "natural" leaders and mediators in self-help programs for change.

Peer counselors have been used four ways: (1) as clerical help; (2) as an adjunct to the counseling program, usually in a narrowly defined role such as tutor or information provider; (3) as an aide in a group setting under direct supervision of a counselor; and rarely (4) as an independent agent with the responsibilities of a counselor.

A group counseling model for peer training emphasizes self-awareness, interpersonal and communication skills, and an introduction to counseling skills for higher levels of involvement. The model is theoretically grounded in applied and social learning theory, with attention being given to affective and cognitive development. The training program is based on principles of peer group behavior; the power of peer influence is directed toward positive, effective, and rewarding life skills. Peer counselors are models for their peers; positive behavior is encouraged and developed in the training and exhibited by the peer counselors to influence their contemporaries.

V. Delworth evaluated peer counseling programs to ascertain why they are not more effective in school settings. He concluded that the major failure lies in the fact that these individuals are trained to maintain the status quo of the school. In most of the programs surveyed, peer counselors operate under the direct supervision of the counselor and within the formal hierarchical school structure. This makes it difficult to have an effect on "problem" students whose values are different from those represented by the peer counselors.

The necessary elements for an effective paraprofessional or peer program are that (1) the selection process must identify the natural leaders and helpers, (2) the training must provide access to "system entry" skills, (3) involvement in all aspects of the organization must be encouraged, (4) this involvement must be developmental, and (5) community among the peers must be built.

PEER GROUP THERAPY

Therapy done in a group by lay people who share common problems is known as peer group therapy. Peer group therapy was lifted to major importance with the beginning of Alcoholics Anonymous (AA).

Peer group therapy uses a high level of self-disclosure, rigorous honesty about personal responsibility for actions done, admission of past wrongs to a member of the group or the group itself, readiness to give up old ways of behaving, the making of amends to people who have been harmed, the turning over of one's will and life to the care of some higher power, and assistance to others as a means of helping the member stay sober.

Other peer groups use much the same format, with some requiring more confrontation. Some groups reported on in the literature are simply peers, but most, other than AA and AA-type groups, also have lay leaders who are minimally trained by someone with a psychology background.

All told, approximately 1,500,000 people are involved in peer group therapy in AA and AA-type groups.

Peer group therapy is also practiced in groups such as Synanon, Daytop, and other communities set up to free people of drug use and to provide continuous living support thereafter. They are structured around an environment of deep love and concern but have a highly confrontative atmosphere with a constant demand for rigorous honesty in every aspect of the ex-addicts' daily lives. Communal living and constant confrontation seem to be required for addicts, whereas alcoholics do not find this necessary.

Many other self-help groups practice peer group therapy: Make Today Count (for cancer sufferers) and Grow groups (started in Australia and now in the United States for people who want to improve their emotional functioning) are two of the larger organizations. In addition, there are groups organized by parents or adults who need help facing a problem with an illness or handicap. Examples are United Cerebral Palsy and the Muscular Dystrophy Association.

A national clearinghouse for all self-help organizations is the Self-Help Center of Evanston, Ill. There are nearly 40 other self-help centers in various stages of operation or development across the country. An estimated 500,000 self-help groups in the United States serve as many as 5 million people.

PEER INFLUENCES

High-quality peer relationships are important for all aspects of the development and well-being of children and adolescents. Compared with interaction with adults, interactions with peers tend to be more frequent, more intense, and more varied throughout childhood and adolescence. Traditionally, however, the relationships between children and adults have been viewed as the most important vehicle

for ensuring effective socialization and development. Child-child relationships have been assumed to be, at best, relatively unimportant and, at worst, unhealthy influences. Such views were mistaken. Prominent theorists such as Sigmund Freud, George H. Mead, Jean Piaget, Erik Erickson, Lawrence Kohlberg, and many others have argued that high-quality peer relationships are essential for an individual's development and well-being, and hundreds of research studies have validated their views (see Bukowski, Newcomb, & Hartup, 1996; Johnson, 1980; Johnson & Johnson, 1999; Ladd, 1999).

In their interactions with peers, children directly learn attitudes, values, skills, and information unobtainable from adults. Positive peer relationships continue to have a critical impact throughout a person's life.

Prosocial and Antisocial Behavior

Interaction with peers provides support, opportunities, and models for prosocial or antisocial behavior. Peers provide the norms, models, and motivation for engaging in prosocial actions as well as the opportunity for doing so. It is while interacting with peers that a person has the opportunity to help, comfort, and give to others. Without peer interaction, many forms of prosocial values and commitments could not be developed. There is a solid and established link, furthermore, between prosocial behavior and peer acceptance. Rejection by peers tends to promote antisocial actions, such as instrumental and impulsive aggressiveness, disruptiveness, and other negatively perceived behavior.

Impulsiveness

Children frequently lack the time perspective needed to tolerate delays in gratification. However, as they develop and are socialized, the focus on their own immediate impulses and needs is replaced with the abilities to (1) take longer time perspectives, and (2) view their individual desires from the perspectives of others. Peers provide models of, and expectations, directions, and reinforcements for, learning to control one's impulses.

Perspective-Taking Ability

Primarily through interaction with one's peers, egocentrism is lost and increased perspective-taking ability is gained. Perspective taking is a critical competency for cognitive and social development. It has been related to the ability to present and comprehend information, constructively resolve conflicts, willingly disclose personal information, help group problem solving, and display positive attitudes toward others in the same situation. All psychological development may be described as a progressive loss of egocentrism and an increase in ability to take wider and more complex perspectives.

Autonomy

In making decisions concerning what behavior is appropriate, autonomous people tend to consider both their internal values and the expectations of other people, and then to respond in flexible and appropriate ways. Autonomy is the result of the internalization of values derived from previous caring and supportive relationships (internalized values provide guides for appropriate behavior and self-approval) and the acquisition of social skills and social sensitivity (which provide accurate understanding of others' expectations for one's behavior). Peer relationships have a powerful influence on the development of values, social skills, and social sensitivity. Children with a history of isolation from or rejection by peers often are inappropriately other-directed. They may conform to group pressures even when they believe the recommended actions are wrong or inappropriate.

Identity

Throughout infancy, childhood, adolescence, and early adulthood, a person moves through several successive and overlapping identities. Physical, cognitive, and social development and broader experiences and responsibilities all cause changes in self-definition. The final result is a coherent and integrated identity. In peer relationships, children clarify the similarities and differences between themselves and others, experiment with a variety of social roles that help them integrate their own sense of self, clarify their attitudes and values and integrate them into their self-definition, and develop a frame of reference for perceiving themselves.

Aspiration and Productivity

Peers have a strong influence on productivity and aspirations. Supportive relationships with peers are related to using abilities in achievement situations and to academic competence. Peer rejection predicts school absenteeism, grade retention, and adjustment difficulties. The more one's peers value academic excellence and the higher their academic aspirations, the more likely one is to achieve and to seek out opportunities for higher education.

Psychological Health

The ability to maintain interdependent, cooperative relationships is a prime manifestation of psychological health. Poor peer relationships in elementary school predict psychological disturbance and delinquency in high school, and poor peer relationships in high school predict adult pathology. The absence of friendships during childhood and adolescence tends to increase the risk of psychological disorder. Peer rejection predicts loneliness and emotional distress

while friendships and peer acceptance are related to socioemotional adjustment. Children adapt better to stressful situations when in the presence of friends or familiar peers. *Peer victimization* exists when children are exposed to abusive processes that promote cognitive-affective states such as insecurity, mistrust, or fearfulness. Peer victimization involves aggressors and their victims, and is linked with a number of adjustment difficulties during childhood, including anxiety, loneliness, depression, and school maladaptation.

Promoting Positive Peer Relationships

To promote positive peer relationships, children should first have continuous opportunities to cooperate with peers and occasionally engage in competitions. Second, children should receive specific training in the social skills needed to build and maintain positive relationships. Third, the norms of caring, support, encouragement, assistance, reciprocity, and so forth should be established. The rights and responsibilities of collaborators and friends should be clear. Finally, a set of civic values needs to be taught and inculcated. Those values include commitment to the well-being of others and to the common good, a sense of responsibility to contribute one's fair share of the work, respect for the efforts of others and for them as people, behaving with integrity, caring for others, showing compassion when others are in need, and appreciating diversity.

PEER TUTORING

Any use of students to coach or tutor one another is usually called "peer tutoring," although when their ages differ, the students are not really members of the same peer group.

Comenius, the sixteenth-century Czech educator, observed what is a routine finding on peer tutoring today, that those doing the tutoring learn more than those who are tutored.

The appeal of peer tutoring for modern educators lies in its effectiveness as a teaching/learning method, rather than in its potential economies. Research studies have been universally supportive of the method.

In a review of research, A. Elliott arrived at the following explanations for the efficacy of peer tutoring:

1. Peer tutoring increases the percentage of time spent on teaching in the classroom period.
2. Peer tutoring provides learners with more feedback as to their performance and provides it promptly.
3. Peer tutoring increases time spent in student talk and decreases time spent in teacher talk.
4. Tutors enjoy an enhanced sense of competence and personal worth.
5. Tutors are enabled to view the teaching/learning situation from the teacher's position and thus are led to make the classroom psychological climate more cooperative and less suppressive and authoritarian.
6. Tutors are able to identify problems of learning and adjustment that have been overlooked by teachers.

Henry C. Lindgren

PERCEPTION

Perception refers to the experience of obtaining sensory information about the world of people, things, and events, and to the underlying process.

The Classical Theory

Successive British empiricist philosophers from Hobbes to Berkeley to Mill viewed all perceptions as learned assemblies of simpler sensory ideas. Scientific study began in 1838 when J. Müller identified the specific part of the nervous system underlying each modality; H. von Helmholtz (Müller's student) subdivided those modalities into elementary sensations, each due to a specific receptor nerve cell reacting to selected stimulation. Thus, the eye's *retina* contains receptors for long, middle, and short wave lengths

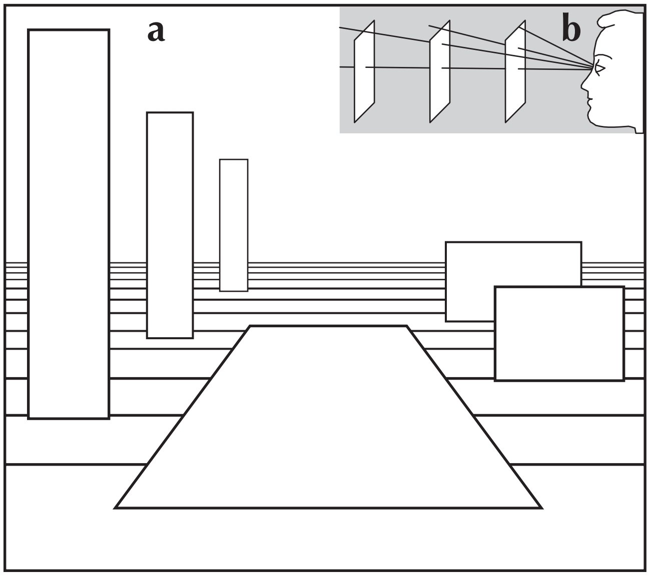

Figure 1. Two dimensional images of a three-dimensional world. (a) Classical pictorial cues to depth and distance. (b) Visual angle as a function of object size and distance.

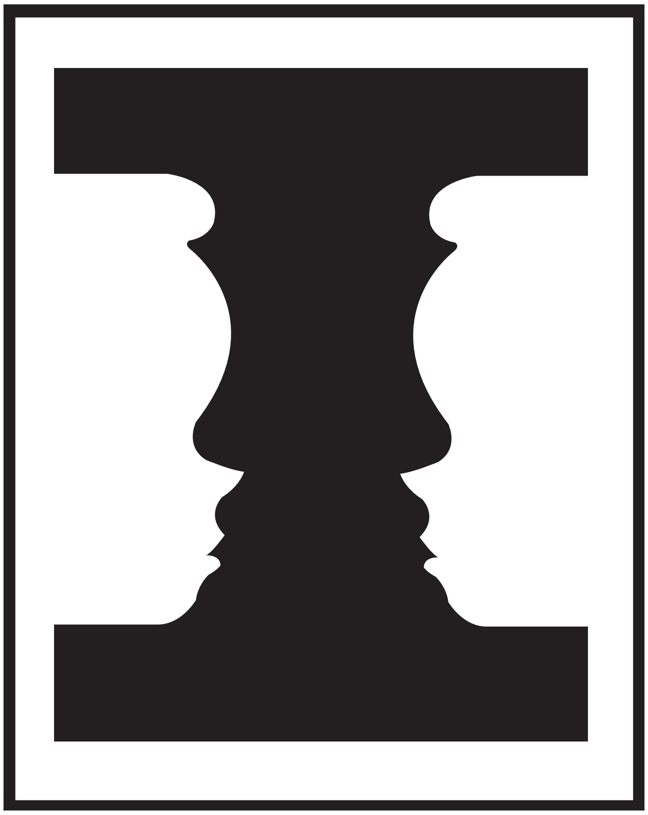

Figure 2. Figure and Ground: When the black pedestal is figure, the white regions are unshaped ground, and when the white faces are figures the black region is unshaped ground.

(L, M, S), presumably providing red, green, and blue points of color sensation.

Most perceived properties—shape, distance, movement, and so forth—are not sensations in this theory, but complex learned perceptions, as considered next.

Things in Space: Depth, Constancies, Illusions

Many different three-dimensional objects can provide the same (two-dimensional) retinal image. However, normal environments offer *depth cues.* (Simple examples, studied by fifteenth-century artists, include the perspective illustrated in Figure 1a, and the occluding intersections shown in Figure 4a.) To classical theory, depth perception rests on memories that the depth cues have acquired. These *associations* involve connections formed between simultaneously active nerve cells in the brain. By using depth cues, illumination cues, and learned rules about how such variables relate the object to its retinal image (see Figure 1b), the perceiver unconsciously infers the object's attributes. When we correctly use whatever cues are present, we thereby achieve *size constancy, shape constancy, color constancy,* and so forth. Misperceived attributes, or *illusions,* presumably result from mistaking some pattern for a cue it is not.

In this theory, all perception is learned. Independent sensory receptors analyze stimulation into elementary sensations, and by associating those sensations into perceptual structures, the brain mirrors the environment.

The theory's first problem is that some animal species can respond appropriately to visual depth *without prior visual experience* (E. Thorndyke, chicks; E. J. Gibson and R. Walk, other species); How they do so, however, remains undetermined.

Organization, Figure/Ground, and the Gestaltist Argument

To *Gestalt* theorists (notably M. Wertheimer, W. Köhler, and K. Koffka) the visual system responds directly to the stimulating energies' overall *configuration* (or Gestalt), not to a point-by-point analysis. In Figure 2, an example of E. Rubin's figure–ground phenomenon, only one region, the pedestal or the pair of faces, is *figure* and has a recognizable shape at any time, while the other is *ground,* extending behind the figure's edge. *Laws of figure–ground organization* therefore determine what objects we see: By the *law of good continuation,* for example, a familiar letter is concealed and revealed in Figures 3a and b, respectively, and the cube in Figure 3d is only a flat pattern in 3c.

Gestalt theory did not replace its opponent. Figure–ground properties and organizational "laws" might just be environmental likelihoods, as E. Brunswik proposed, while no Gestaltist theory explaining such phenomena survives. Research to quantify organizational "laws" does continue, like that by M. Kubovy, as do attempts to replace these laws with the more general principle that one perceives the sim-

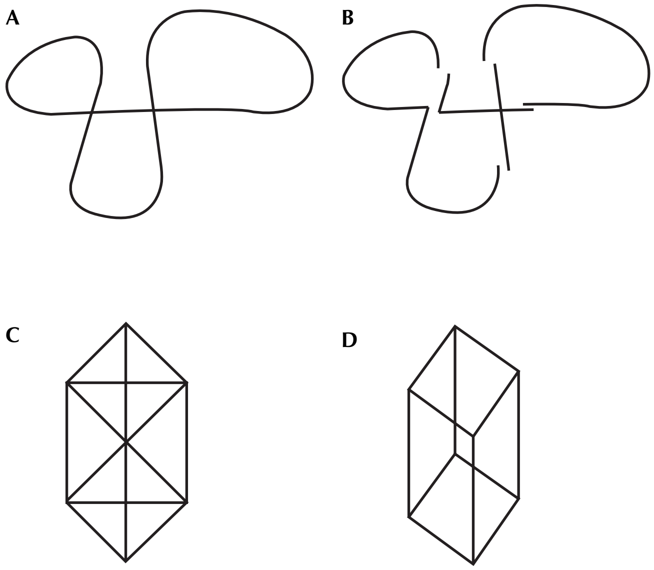

Figure 3. At (a), *good continuation* obscures the familiar shape ("4") that is revealed at (b). The pattern at (c) is *simpler* as a flat pattern than that at (d).

plest organization that fits a particular stimulus pattern—for example, Figure 3c is simpler as a flat pattern than 3d. Such efforts have been undertaken separately by the present author and by F. Attneave, and pursued by E. Leeuwenberg and colleagues. But a general theory of configurations, compatible with modern neurophysiology, has not yet appeared.

Direct Perception Versus Inference

To replace both Helmholtzian and Gestalt approaches, J. J. Gibson proposed that viewers moving through natural environments receive stimulus information that remains constant despite changing conditions (distance, slant, etc.). This allows *direct perception* of objects and layout: No inferences from depth cues are needed. This direct approach generated several sophisticated mathematical analyses of available information, most recently by J. Koenderink and A. van Doorn, and experimental studies of its use (whether "directly" or otherwise), notably by W. Warren.

But the Gibsonian approach, too, has not replaced Helmholtzian inference: Depth cues certainly appear to work, as in pictures and false-perspective illusions, even when they are opposed by motion-generated information signaling a flat surface. Like Gestalt theory, it has yet to connect with what we now know about eye and brain.

Modern Neurophysiology

Helmholtz's assumptions about independent receptor neurons and sensations were wrong. To E. Hering and E. Mach, Helmholtz's contemporaries, neuronal interconnections accounted directly for some perceptual constancies and illusions, assertions mostly accepted today. Hering's argument that the elementary colors are not red, green, and blue sensations, but three opponent pairs originating with interconnected cell pairs, was verified by L. Hurvich and D. Jameson (psychophysically) and by R. DeValois and G. Jacobs (using microelectrodes). Mach's proposal of pattern-sensitive interconnections was verified by D. Hubel and T. Wiesel, using microelectrodes to find cells and brain regions with receptive fields selectively sensitive to shapes and motions. (Some properties and objects we perceive surely reflect the output of specific neural mechanisms.) The retina's topography is preserved upward through several cortical levels, with increasing receptive field size and decreasing resolution from V1 to V4; these levels are all mutually connected in both directions, as P. Lennie maps them, so the highest V4 offers a context-affecting entry level, V1.

Such pattern-sensitive structures and top-down interactions must change our approach to perceptual theory.

Attention and the Moving Eye

Only the small retinal center (the *fovea,* ca 2°) obtains detailed visual information. Within single foveal glances, items that are unfamiliar, unexpected, or of no interest to the viewer may go undetected. To see more, the viewer aims and executes rapid intentional eye movements (*saccades*), getting glimpses of about 1/5sec/glance. Integrating such successive glimpses into a unified perception of an object or scene is not automatic or all-inclusive, as movie editors know well: Figure 4 remains ambiguous when attending point b, even *after* attending a. Detailed information that has been looked at but not *encoded* (stored in working memory, as G. Sperling showed) is usually not followed up. Per-

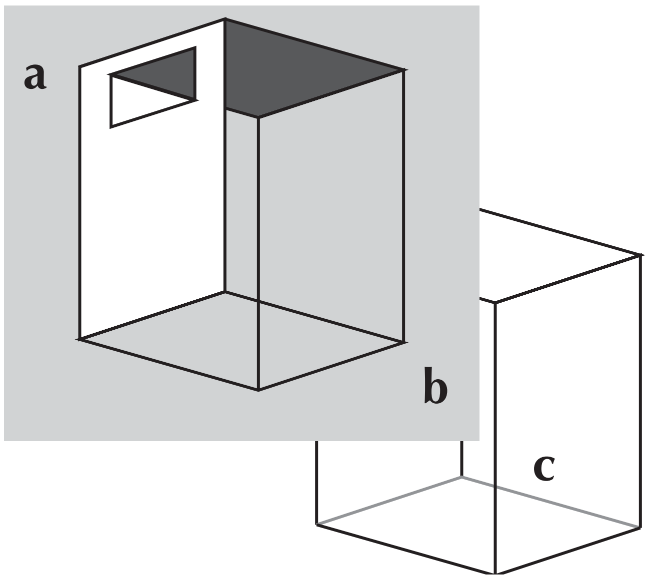

Figure 4. Occlusions at (a) show the white leftmost region to be in front. At lower right (b) the same figure is ambiguous, and can be readily reversed, as in the cube partially shown at (c).

ception is a directed activity, and brain imaging is about to tell us how the different regions participate in attentive perceptual inquiry.

Julian Hochberg
Columbia University

PERCEPTUAL CONTROL THEORY

"Perceptual control theory" is a name adopted by a group of scientists interested in the feedback-system organization of human and animal behavior to distinguish their work from the control theory field of servo engineers. The members are engaged in the development and application of the thesis advanced in W. T. Powers's (1973) book, *Behavior: The Control of Perception.* While a majority of this group are psychologists, it also includes biologists, sociologists, systems engineers, mathematicians, and members of other professions—all finding themselves able to communicate with the common language of Powers's theory, a rather unusual experience in this age of high specialization.

One member of the group, Richard Marken, observed that Powers has not one but two accomplishments to his credit. First, he discovered, or noted, that behavior is the control of perception, contrary to what psychologists have believed ever since Descartes. For Descartes, the environment controlled behavior in the sense that he believed perception of phenomena of the environment stimulates or triggers behavior by entering sensory receptors to set off reflex responses in the organism. Second, Powers developed a theory to explain how behavior does work, showing that feedback-control theory can account for how perceptual variables are maintained against external influences/disturbances by control systems, whether in organisms or robots. The theory he developed finally provided a coherent mechanism for the phenomenon of homeostasis, which had been observed much earlier by biologists but had remained an inexplicable phenomenon.

Although biologists had gradually accepted self-regulatory—homeostatic—mechanisms after Bernard as applying to many bodily functions, the idea that the same principles could account for mental phenomena gained ground more slowly. However, beginning in the 1940s a number of scientists, such as Norbert Wiener, began to suggest that such principles could explain certain aspects of behavior, if not all. Finally, in 1960 the team of W. T. Powers, R. K. Clark, and R. L. McFarland published *A General Feedback Theory of Human Behavior,* which presented the first fully comprehensive view of how all behavior could be accounted for by an integrated assembly of hierarchically-ordered feedback control systems. This work then led to Powers's 1973 book.

The basic scheme is as follows. Behavior occurs via a system comprised of a closed feedback loop in which a variable perceptual signal (PS) is held to a specified value—reference signal (RS)—by the workings of a comparator (C). The comparator subtracts the value of the reference signal from the value of the perceptual signal to obtain an error signal (ES) that is fed into an output mechanism capable of affecting the perceptual signal in such a way as to counteract any disturbance (D) coming from the environment. It does so by driving the perceptual signal back toward (maintains it at) the reference value. The system works to keep minimizing the errorsignal, and in so doing it controls the pertinent, perceived aspect of the environment as a byproduct. Perceptual variables in organisms derive from sensory signals.

Reference signals are previously stored sensory signals. Output mechanisms are ultimately muscles and glands. Powers pointed out a number of examples of feedback circuitry in neuroanatomy in his book and has continued to find additional anatomical evidence in his further work.

Figure 1 shows the feedback loop outlined in its simplest form.

The same scheme is repeated in hierarchical fashion in which the sensory signal is relayed to higher order systems and the output of the order above determines the RS of the order below. This simple schema may be effectively applied to a host of everyday behaviors to explain what is happening. A popular illustration is the action of driving a car. The driver keeps the car in its lane against external disturbances such as wind, curves, bumps, and so forth by monitoring the relationship between the front of the car and the edge of the road, both of which are perceptual variables reducible to a higher order variable: the constancy of that relationship. The latter is thus the presumptive perceptual signal of interest. It is matched in the brain to the reference signal; that is, the desired condition of that relationship, the result being the continual flow of error signals that are minimized by the actions of the driver on the steering wheel.

Powers showed that this analysis could be quantified in

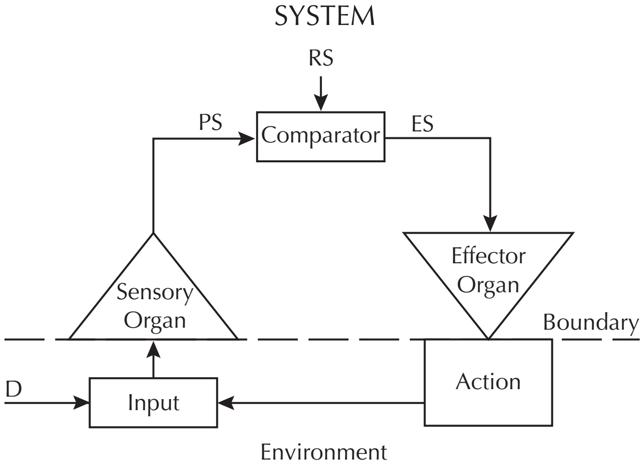

Figure 1. Feedback loop.
Source: Adapted from W. T. Powers, 1973, *Behavior: The Control of Perception.*

simultaneous equations as PS = O + D and ES = PS – RS, where D represents a disturbing condition in the environment, and O, the output of the system, is some function of ES as determined by the properties of the particular system. He applied these equations to many different analyses of behavioral phenomena, adding constants as appropriate to specific systems, and created a number of computer simulations of various types of behavior showing that human actions can be imitated by programs using his functions, the implication being that if a feedback model, and only a feedback model, imitates a human performance, it suggests that the behavior is feedback controlled.

The perceptive reader might have noticed in the above that Powers has also solved the problem of purpose, or intention, that has been a dilemma for stimulus–response psychologists. It is identical with the reference signal. The control system realizes what one intends as the organism's action brings what is being perceived to match the specification that is to be perceived. Powers went on to propose hypothetical answers to many other questions that one might raise about the nature of behavior. He sketched out a hierarchy of control systems to account for the complexity of behavior, in which individual control systems of each level receive their reference signals from the output of systems of the level above.

Another proposal is that of an organizing–reorganizing system powered by an intrinsic system comprised of genetically determined reference settings. He postulated that if any "readings" in the intrinsic system go into an error state (i.e., indicate physical malfunctioning), the reorganizing system would be triggered to inject random signaling into the control-system hierarchy to bring about changes in neural circuitry which, when successful in controlling some new (for that organism) condition, constitutes what we regard as learning. His insight was that only random action could afford the chance to produce a new type of action (in a given organism) because any disturbance to conditions already under control would immediately be nullified by existing systems. A moment's reflection leads one to conceive of how the human being comes to have a learned hierarchy in the first place, starting from only an intrinsic system of genetically given life-supporting systems at birth, acting via the reorganizing system upon a growing mass of uncommitted neurons forming and reforming connections as development proceeds.

Other members of this group have gone on to apply Powers's analysis to a wide variety of experiments and applications based upon the idea that living organisms do not control their environments by controlling their outputs, but instead, by controlling their inputs—their perceptions. Much of this work constitutes a significant advance in the testing of hypotheses by quantitative model building and computer simulation rather than by inferences of causality from correlations, as is commonly practiced in contemporary psychology. This work can be accessed through the information net CSGnet; the Control Systems Group homepage, http://ed.uiuc.edu/csg/csg.html; W. T. Powers's web site, http://home.earthlink.net/~powers_w; and other members' home pages.

PERCEPTUAL DEVELOPMENT

The most active investigations about perceptual development focus on infants' visual and auditory capabilities. Researchers who study these topics have demonstrated impressive creativity and persistence in designing research techniques for assessing early abilities. Two representative methods are the following: (1) the habituation/dishabituation method, in which infants decrease their attention to an object that has been presented many times, and then increase their attention when a new object is presented; and (2) the preference method, in which infants spend consistently longer responding to one object than to a second object.

Visual Development

The retina of a newborn is not fully developed, especially in the central region (fovea) where adult acuity is best. A newborn's visual accuity is about 20/600; that is, newborns can see at 20 feet what an adult with normal acuity (20/20) can see at 600 feet. However, acuity improves with age, until it approximates 20/20 vision at about 3 years of age.

Infants who are younger than 1 month of age do not have functional color vision. However, by 3 months of age, they can discriminate among many different colored stimuli.

With respect to distance perception, 6-month-old babies can use both monocular depth information (e.g., shading, interposition) and binocular depth information (e.g., binocular disparity, with each eye registering a slightly different view of the world). By this age, they also tend to avoid the deep side of a visual cliff, thereby demonstrating that they can apply this visual information about distance.

Young infants also demonstrate constancy. For example, a 3-month-old shows some shape constancy, so that an object seems to stay the same shape, even when viewed from a different angle. A 6-month-old shows good size constancy, so that an object seems to stay the same size, even when viewed from a different distance. In contradiction to Piagetian theory, infants display object permanence by about 4 months of age; an object still exists, even when it is hidden behind another object.

Motion perception also develops in the first months of age. For example, by 5 months, babies can make relatively

subtle discriminations in an object's motion. By this age, they also appreciate biological motion, which is the pattern of movement of living things. For example, they can look at a set of moving lights and tell the difference between (1) a pattern of lights representing a moving person and (2) a pattern of random moving lights.

The research on shape perception suggests that infants exhibit several Gestalt laws, such as the law of closure. When adults look at a long rod moving back and forth—but partially concealed by a block—we perceive that the rod is one solid, continuous object, rather than two separate rod fragments. Infants who are 2 months old also display this law of closure, but newborns do not.

With respect to face perception, infants who are 1 *hour* old can move their eyes a longer distance in order to track a facelike stimulus, rather than a stimulus with a scrambled-face design. Infants who are 1 day old will produce more sucking responses to a video of their mother than to a video of a female stranger. These findings have important implications for early face recognition and for the development of emotional attachments.

Auditory Development

Within the topic of auditory development, the majority of the research focuses on speech perception. More than 30 years ago, researchers demonstrated that infants between the ages of 1 and 4 months could distinguish between two similar phonemes, such as /b/ and /p/. We now know that infants can make more than 50 different contrasts between speech sounds. Infants' language environment has an influence on the development of phoneme discrimination. For example, 6-month-old infants reared in an English-speaking environment are highly accurate in distinguishing between two Hindi phonemes, even though English-speaking adults cannot make this particular distinction. However, if the infants continue to be exposed only to English—and not to Hindi—they lose this ability by about one year of age. At this age, they are only sensitive to distinctions that are relevant in their own language environment.

In addition to detecting the differences between speech sounds, infants also appreciate similarities between speech sounds. For example, they reveal an ability that could be called "speech-sound constancy"; that is, they recognize that the phoneme /a/ spoken in a high-pitched woman's voice is the same as the /a/ spoken by a relatively low-pitched man's voice. This ability is important because it allows them to recognize words they have heard before, which had been produced by a different person.

In terms of preferences, 2-day-old newborns can discriminate between their mother's voice and the voice of a stranger. Furthermore, 4-day-old newborns prefer to listen to speech produced in their mother's native language, rather than in another language. For instance, French infants preferred to listen to a stranger speaking French, rather than when the same woman spoke Russian. Newborn infants even prefer to listen to a passage from a children's story that their mothers had read during the last 6 weeks of pregnancy rather than a similar passage from a different children's story. All three studies demonstrate that vocal information is perceived during prenatal development.

By 4 months of age, infants prefer to listen to child-directed language—the exaggerated, high-pitched speech that parents use in speaking to infants—rather than the kind of language directed toward other adults. By 4 months, infants also appreciate that the visual and auditory components of language must be coordinated; the vowel sound from the word "pop" should come from a rounded mouth configuration.

All these auditory skills have important implications for one of the most impressive of cognitive skills: the comprehension and production of spoken language. Developmental psychologists have difficulty explaining how children can rapidly acquire thousands of words between one year of age and the time they start school. The research on infants' auditory abilities demonstrates that they already have a significant head start before they reach their first birthday.

PERCEPTUAL STYLE

A perceptual style means that a person has a characteristic way of perceiving the world. The idea that people perceive the world in different and individual ways is an intriguing one. The uses of color and form by some modern painters in highly individual and somewhat distorted ways have been hypothesized to be based on possible visual defects, so that the artist is truly copying his or her own subjective experience into art. However, this is difficult to prove, as are other hypotheses. Is it truly a perceptual influence or simply a cognitive interpretative one? Somehow, cognitive styles, meaning the way people think, seem a more neutral concept than perceptual styles. Additionally, there is always the problem of reliable and repeatable information.

Young children do seem to perceive the world more globally and as less differentiated than adults do. Not only do they have less developed verbal descriptions, but also their eye and hand movement search patterns are much less differentiated and precise than are those of older children and adults.

Herman Witkin used the concepts of "field independence" and "field dependence" in the 1950s and 1960s to describe individual differences on perceptual tasks. Witkin had three major tasks: an embedded figures task, a rod-and-frame task, and a tilted room task. Field-independent

people can ignore the conflicting visual surround to find a hidden figure (embedded figures) or the true vertical (rod-frame, tilted room). The field-dependent subjects are more influenced by the visual surroundings, leading to worse performance on the embedded figures or dependence on the visual framework rather than the true gravitational one in the other tasks. Performance on the three tasks is related. Witkin also related the results to various personality measures. Field independence and field dependence are still heavily researched areas.

The most reliable "perceptual style" is that of immaturity. Children are less able to differentiate the visual field than are adults. In addition to children, brain-injured adults show these same effects.

PERFORMANCE APPRAISAL

Organizations are concerned with performance. Indicators such as profits, sales, number of widgets produced, number of defective widgets, costs of production, downtime, number and severity of accidents, number and length of absences, and so forth are used in evaluating an organization and the units within an organization. Similarly, performance appraisals evaluate performance of individual employees.

Performance appraisals are used in making administrative decisions, for counseling employees, in training and developing employees, for human resources planning, and in the validation of selection procedures. They are utilized in determining pay increases, in making promotional decisions, and in deciding whether an employee is to be discharged.

There is much discontent with performance appraisal systems. Frequent changes in the methods used for making appraisals, and even abandonment of them, are common occurrences.

History

Informal appraisals of performance have been universal throughout history. Formal appraisal systems have been used since at least the third century A.D. Industrial applications can be traced back to Robert Owens, who introduced them in Scotland early in the nineteenth century. The military forces of the United States adopted performance appraisals in 1813, and the federal government did so for its civilian personnel in 1842.

During the twentieth century, the growth of performance appraisal systems has been relatively rapid. Psychologists have played an active role in the development and application of these systems. In recent years, psychologists have become concerned with the applications of such systems and have been involved in efforts to improve their use.

Subsequent to the passage of the Civil Rights Act of 1964, performance appraisal systems have been subjected to legal challenges. In a number of rulings, federal court judges have found that such systems discriminate against minorities and other groups protected by the law.

Methods

For appraising performance, a variety of methods have been developed. From the results of surveys of business and of government organizations, those in use can be classified as essay, rating scales, combined essay and rating scales, and objectives-based. Essays are essentially narrative reports on the performances of individual employees. They describe and evaluate performance. Rating scales are designed to quantify performance, either overall, on separate dimensions, or on a combination of both. Objectives-based appraisals are used in concert with management-by-objectives (MBO) approaches that have been adopted by many organizations in recent years.

Several varieties of rating scales have been developed. The most prevalent are known as "graphic" rating scales and are characterized by requiring the rater to indicate a ratee's performance as to some characteristic—for example, "integrity."

Another, more complex method of rating is referred to as "forced choice." In using this method, a rater is required to select a word or phrase from two or more that best describes the person being rated. The words or phrases composing such combinations are statistically determined, as are the numerical values assigned each word or phrase.

A third rating method, developed during World War II, is known as "critical requirements" or, more commonly, as "critical incidents." The method is based on descriptions of behaviors that reflect either effective or ineffective performance. Once these critical incidents have been collected and edited for a particular occupation, they form the basis for a checklist of behaviors, the critical requirements that can be used in evaluating performance.

Behaviorally anchored rating scales (BARS) are a relatively recent addition to rating scale methods. They emphasize participation by the raters in developing the scales, a procedure called "retranslation," mathematical scaling, careful observations of performance, and logging of observations by the raters.

Behavioral observation scales (BOS) are the most recent addition to rating scale methods. Using critical incidents, behaviors important to effective performance in an occupation are first identified. They are grouped into categories by persons familiar with the work or by a statistical method

called "factor analysis." The items describing the behaviors are designed so as to obtain estimates of the frequency with which the behaviors occur. A scoring method provides for total scores by categories of performance and for a total score across categories. Raters using the method are forced to focus on specific behaviors crucial to effective performance in making their observations and recording their observations.

All rating scale methods depend on some person or persons making judgments of performance. Consequently they are essentially subjective. In contrast, objectives-based appraisal methods focus on collecting information that furnishes objective information concerning performance, for example, sales, quantity and quality of goods produced, or frequency of absences.

Research

It is generally recognized that raters tend to make many errors. Among the common errors is the "halo effect," which is a tendency to rate a person the same on all characteristics being rated even though the ratee may perform differently on different aspects of a job. Another common error is referred to as "leniency," a tendency to rate all ratees more favorably than their individual performances would warrant.

It is a common practice in organizations to have supervisors rate their subordinates. Alternative sources, for example, peers, subordinates, outsiders, and the ratee himself or herself, are available.

To develop and validate an appraisal system properly, considerable research is required. The procedures are highly technical and require professional expertise. Unfortunately, many appraisal systems are developed by persons who lack essential knowledge and skills, and thus the validity of such systems is subject to challenge.

After an appraisal system has been implemented, an organization may want to determine the extent to which the system is meeting its objectives. Such an evaluation requires research that may entail extensive collection and analysis of data.

The use of performance appraisals in counseling employees is a relatively recent development. That both judging employee performance and counseling employees on how to improve performance can produce difficulties for a manager seeking to accomplish these objectives became apparent in a series of studies conducted in the General Electric Company. The studies clearly showed that mutual goal setting by a supervisor and a subordinate and avoidance of criticizing the latter's performance are essential if improved performance is to be achieved.

Application

Implementing and maintaining a performance appraisal system requires much effort and involves many of the resources of an organization. Performance appraisal poses many issues, and considerable mutual education may be required if practitioners and researchers are to function as a team.

Appraisal systems tend to depend on ratings of performance, which are inherently subjective. The many attempts to objectify ratings have had little, if any, success. However, objective methods for appraising performance also have many limitations.

The legal issues involving discriminatory aspects of performance appraisal systems are relatively recent. Though future developments with respect to the legal aspects of performance appraisals are difficult to predict, it would appear that organizations and others concerned with such systems, psychologists in particular, must familiarize themselves with viewpoints expressed by the courts and keep abreast of pertinent developments.

PERFECTIONISM IN GIFTED ADOLESCENTS

While many gifted students find special programs for their academic achievements challenging, some gifted students are overwhelmed by the simplest of academic demands. These gifted students are often viewed as lazy. While this label may occur as early as junior high school, problems with academics may not appear until high school or even college.

There are multiple reasons for being seen as lazy, including learning disabilities, attention-deficit/hyperactivity disorder, drugs, psychosis, a death, or even a divorce. Many lazy students are early adolescents. They are extremely bright and sensitive and were often the teacher's favorite in elementary school. These gifted early adolescents suffer from a crippling triad of an endless drive for perfectionism coupled with an intense fear of failure, which then triggers an overwhelming shame. In addition, they fear their own unresolved anger and aggressiveness, which become fused with their assertion and prevent them from comfortably asserting themselves in competitive situations.

Self psychology and intersubjectivity, with their emphasis on the early mother–child relationship, help us focus on the child's need to please his or her parents as a major source of gifted individuals' struggle with being judged as lazy. However, only by understanding the entrenched intrapsychic struggle, or the infant morality system (IMS), can one truly help these gifted individuals to overcome their struggle with perfectionism and accompanying issues and, thus, to attain their full potential.

The IMS starts during infancy. The more brilliant the child, the earlier this system of judgment begins and, hence, the more primitive the child's judgments. This system is thus founded on "black and white," "all or nothing," perfectionistic, rigid, cruel, harsh, and unrelenting judgments, which the developing gifted child directs toward him/herself and his/her world. In addition, in trying to develop a sense of order in a chaotic world, these highly sensitive children take responsibility for everything. This entire primitive and judgmental system becomes part of their unconscious life.

Between 3 to 5 years of age, as young children start to integrate into their families, they often give up parts of themselves—some of their thoughts, comments, and actions—in order to fit within the family illusions. While acceptance of the family illusions provides some protection from being abandoned, they, unfortunately, lose a core part of themselves.

Although this IMS is entrenched well before a child's entrance into elementary school, the inherent self-criticalness continually undermines the developing child's self-esteem. Their perfectionism makes it difficult for these brilliant children to hold onto positive comments, whether from teachers, parents, or peers. At the same time, they experience negative comments or interactions as an assault on their budding sense of self.

For most gifted children, everything comes easily during elementary school. However, excessive parental intrusions often prevent fragile gifted students from learning effective problem-solving techniques. In addition, these gifted students may not learn how to deal with boredom, frustration, and delayed gratification—hallmarks of a competent, successful student.

At some point, sometimes as late as college, these gifted students hit a wall. Not knowing how to deal with boredom, frustration, and delayed gratification, they become overwhelmed. Possessing no effective problem-solving skills, other than being "bright" or "cute," these gifted students suddenly find themselves devastated by their first failure. As a consequence, these gifted students, especially early adolescent males, just give up. Suddenly, there are a multitude of excuses for not completing their homework or studying for a test. They become "lazy." With a precipitous drop in their self-esteem, these students frequently become involved with angry, rebellious peers.

Another way to avoid dealing with their rigid perfectionism is to become engaged in self-defeating games. One student made going to college into a joke. He never went to class, never turned in any homework, and never studied for tests. Receiving Cs for his work, he bragged about having done so well with absolutely no work. This young adult's struggle with perfectionism also highlights how these difficulties go beyond academics. During this time, he wanted to buy a very expensive sports car with a six-speed manual transmission. After stalling a friend's car only once during an hour-long practice with a stick shift, and in spite of a lifelong desire to drive a stick shift, he bought his dream car without a stick shift.

An additional area of difficulty for these very mild-mannered, gifted students is their inability to deal with anger. Often, they come from families in which anger is not dealt with comfortably. As a consequence, these students often confuse assertion with aggression. When they try to do well, they feel that they will hurt other students. One teenager who was getting Cs at an all-girls high school said,

> If I start to get As, one of my classmates who used to get an A is going to get a B, then another one of my classmates who used to get a B is going to get a C, another one of my classmates who used to get a C is going to get a D, another one of my classmates who used to get a D is going to get an F, and another one of my classmates who used to get an F is going to fail out of school and it's all my fault and they are going to hate me!

As this student learned to be more comfortable with her assertion and competitiveness, her grades improved drastically.

This entry has attempted to show the reader how, independent of parental influence, perfectionism and fear of failure can be severely debilitating to some gifted teenagers. Intellectually, gifted teenagers often understand their parents' desire for them to achieve, as well as their own struggles with being competitive. However, articulating the primitive nature of their intrapsychic conflicts helps them consciously work on lessening their own internal struggle with perfectionism and their fear of failure. In addition, they must address their fear of being seen as defective, as well as being overwhelmed by the ensuing shame, which they experience as paralyzing.

Poor self-esteem is another important issue for the gifted student. As adolescents often respond better to actions rather than to words, walks, sharing food, and playing boardgames or cards are often helpful in lessening the crippling and overwhelming sense of perfectionism. Once again, it is the crippling need to be perfect, as well as the incredible fear of an imagined catastrophic failure and the resulting overwhelming shame that often drives gifted teenagers to become lazy students.

UCLA School of Medicine

PERFORMANCE TESTS

Performance tests require overt, active responses, such as motor or manual behaviors. Such tests frequently measure motor coordination, speed, or perceptual or motor skills. Because of their usual deemphasis on language skills, perfor-

mance tests have proven useful in the assessment of the physically handicapped, particularly the deaf. A common performance test is a typing test that measures how quickly and accurately one can type. A nonperformance measure of typing might ask multiple-choice questions about typewriter parts, positions of the keys, or selection of font, but would not include actual typing performance.

One of the earliest and most popular performance tests is the Sequin formboard, designed for assessment and sensory-motor training of the mentally retarded. This test requires that 10 differently shaped pieces be placed into correspondingly shaped holes; for example, the round peg must be placed in the round hole. More complex formboards also have been developed. Another classic performance test, the Kohs Block Test, developed in 1923, requires subjects to copy patterns by placing cubes with differently colored sides together. The Porteus Maze Test, originally developed in 1914 as a measure of foresight and planning ability, contains sets of mazes graded in difficulty. These early tests, and others like them, continue to be used on IQ tests such as the Stanford-Binet and Wechsler tests.

The Wechsler intelligence tests produce three IQ scores: verbal, performance, and full scale. The full-scale IQ is a combination of verbal and performance subtests, with the performance subtests requiring subjects to perform tasks such as assembling puzzles, forming blocks into patterns, and arranging pictures in a logical sequence. Analyses of the profile or pattern of the subtests and the verbal and performance IQ scores are frequently carried out to provide descriptions of cognitive strengths and weaknesses and insight into possible localization of brain dysfunction and personality factors. For example, sociopaths and people with left-hemisphere damage are believed to tend to score higher on performance than on verbal items.

Performance tests have been used extensively by the military (for example, flight training simulators to measure pilots' skills) and in business (for example, typing tests). In nonacademic settings, performance tests, when obviously related to job skills, generally are acceptable to those being tested for hiring, placement, retention, or promotion considerations. Academic settings also use performance tests, for example, tests of penmanship and oral reading and writing skills (based upon assessing "work samples").

Although performance tests frequently have greater face validity, nonperformance paper-and-pencil tests remain the most commonly used test format. The paper-and-pencil tests, when administered to people sufficiently experienced in this format, can provide measurements that are valid, less expensive, and more conducive to group testing.

PERSONAL CONSTRUCT THEORY

Personal Construct Theory (PCT) represents a coherent, comprehensive psychology of personality that has special relevance for psychotherapy. Originally drafted by the American psychologist George Kelly in 1955, PCT has been extended to a variety of domains, including organizational development, education, business and marketing, and cognitive science. However, its predominant focus remains on the study of individuals, families, and social groups, with particular emphasis on how people organize and change their views of self and world in the counseling context.

At the base of Kelly's theory is the image of the *person-as-scientist,* a view that emphasizes the human capacity for meaning making, agency, and ongoing revision of personal systems of knowing across time. Thus, individuals, like incipient scientists, are seen as creatively formulating *constructs,* or hypotheses about the apparent regularities of their lives, in an attempt to make them understandable, and to some extent, predictable. However, predictability is not pursued for its own sake, but is instead sought as a guide to practical action in concrete contexts and relationships. This implies that people engage in continuous extension, refinement, and revision of their systems of meaning as they meet with events that challenge or *invalidate* their assumptions, prompting their personal theories toward greater adequacy.

Kelly formally developed his theory through a series of corollaries, which can be broadly grouped into those concerned with the *process* of construing, the *structure* of personal knowledge, and the *social embeddedness* of our construing efforts. At the level of process, PCT envisions people as actively organizing their perceptions of events on the basis of recurring themes, meanings attributed to the "booming, buzzing confusion" of life in an attempt to render it interpretable. By punctuating the unending flow of experience into coherent units, people are able to discern similarities and differences of events in terms that are both personally significant and shared by relevant others.

At the level of structure, PCT suggests that meaning is a matter of contrast—an individual attributes meaning to an event not only by construing what it *is,* but also by differentiating it from what it *is not.* For example, a given person's unique description of some acquaintances as "laid back" can only be fully understood in the context of its personal contrast—say, "ambitious" as opposed to "uptight." At a broader level, individuals, social groups, and whole cultures orient themselves according to (partially) shared constructs such as "liberal versus conservative," "pro-life versus pro-choice," and "democratic versus totalitarian," which provide a basis for self-definition and social interaction. Especially important in this regard are *core constructs,* frequently unverbalizable meanings that play critical organizing roles for the entirety of our construct systems, ultimately embodying our most basic values and sense of self. Finally, at the level of the social embeddedness of our con-

struing, PCT stresses both the importance of private, idiosyncratic meanings and the way in which these arise and find validation within relational, family, and cultural contexts.

To a greater extent than other "cognitively" oriented theories of personality and psychotherapy, PCT places a strong emphasis on emotional experiences, understood as signals of actual or impending transitions in one's fundamental constructs for anticipating the world. For example, individuals might experience *threat* when faced with the prospect of imminent and comprehensive change in their core structures of identity (e.g., when facing dismissal from a valued career, or abandonment by a partner they counted on to validate a familiar image of themselves). Alternatively, people might experience *anxiety* when confronted with events that seem almost completely alien and uninterpretable within their previous construct system. This attention to the delicate interweaving of meaning and affect has made PCT an attractive framework for contemporary researchers and clinicians concerned with such topics as relational breakdown, trauma, and loss, all of which can fundamentally undercut one's assumptive world, triggering a host of significant emotional and behavioral responses.

As an approach to psychotherapy, PCT stresses the importance of the therapist making a concerted effort to enter the client's world of meaning and understand it "from the inside out," as a precondition to assisting with its revision. In this way the therapist does not assume to be an expert who guides clients toward a more "rational" or "objectively true" way of thinking. Instead, he or she works to help clients recognize the coherence in their own ways of construing experience, as well as their personal agency in making modifications in these constructions when necessary. At times the therapist prompts the client's self-reflection by making use of various interviewing strategies such as the laddering technique to help articulate core constructs, or narrative exercises such as self-characterization methods, as a precursor to experimenting with new ways of construing self and others. Such changes may be further fostered by the creative use of in-session enactment, fixed role therapy (in which clients "try out" new identities in the course of daily life), and other psychodramatic techniques.

A unique feature of PCT is its extensive program of empirical research conducted by hundreds of social scientists around the world. Most of this research has drawn on *repertory grid methods* (see also "Repertory Grid Methods"), a flexible set of tools for assessing systems of personal meanings, which have been used in literally thousands of studies since Kelly first proposed the concept. By providing visual and semantic "maps" of an individual's construct system and its application to important facets of one's life (e.g., relationships with friends, partners, and family members), grids have proven useful in both applied and research settings. Among the many topics investigated using this method are the body images of anorexic clients; the ability of family members to understand one another's outlooks; children's reliance on concrete versus abstract construing of people; and the degree of commonality of work team members in their construing of common projects.

Finally, it is worth emphasizing that PCT, despite its status as the original clinical constructivist theory, remains a living tradition that continues to attract scholars, researchers, and practitioners from a broad range of disciplines. More than many other theories, it has established a sizable following and annual conferences outside of North America, with vigorous programs of training, research, and practice in countries as diverse as Australia, Germany, Spain, and the United Kingdom. As it has grown in influence, it has also begun to articulate with other, more recent "postmodern" traditions of scholarship, including other constructivist, social constructionist, and narrative therapy approaches. While these various perspectives differ in some respects, each draws attention to the way in which personal identity is constructed and transformed in a social context. Likewise, each focuses on the role of language in defining reality, and each suggests a collaborative role for the psychotherapist attempting to assist clients with the problems of living.

PERSONALITY AND ILLNESS

Personality is an overarching construct used to identify the characteristics (e.g., traits, motives, interests, goals) that influence an individual's unique pattern of thinking, emoting, and behaving. Over the centuries physicians have observed an association between these personal characteristics and predispositions toward illness. Hippocrates, the father of medicine, in 404 B.C.E. concluded, "There is no illness of the body apart from the mind." The ancient English physician Parry of Bath observed, "It's more important to know what sort of person has a disease than what sort of

disease a person has." And Sir William Osler, the nineteenth century Canadian physician, often remarked, "The care of tuberculosis depends more on what the patient has in his head than what he has in his chest."

Illness-Prone Personalities

There has been a great deal written about illness-prone personalities. The general assumption is that the beliefs and emotional lives of different personalities predispose them to certain illnesses. The illness-prone personality for which there is the greatest amount of research support is the coronary-prone personality, first identified by Meyer Friedman and Ray Rosenman (1974). The criteria used in identifying this personality include a behavioral syndrome, referred to as the Type A behavior pattern, and certain beliefs regarding one's self-worth. Coronary-prone individuals believe that their worth is derived solely from their accomplishments and that their success results from being able to more, and to do it faster, than the next person. Consequently, they are said to be suffering from "hurry sickness." Because they are driven to produce, they grow impatient with tasks that require delayed responses, and because they frequently engage in multitasking, they are more likely to experience frustration and hostility from encountered barriers to success. Persons possessing these personality characteristics were said to have an increased risk of coronary artery disease. Recent research conducted independently at three universities, however, presents a more complex picture. Accordingly, the increased risk for heart attacks occurs only when Type A characteristics are accompanied by a cynical distrust of others and a tendency to inhibit hostile feelings. Furthermore, this tendency to experience greater amounts of hostility than normal is associated with a significant increase in mortality across all diseases, not just coronary artery disease. In frustrating situations, hostile people dump more epinephrine and norepinephrine into their bloodstreams and wind up with higher blood pressure.

Other illness-prone personalities have been discussed in the literature, though research evidence for the existence of these personalities is much weaker. Considerable attention has been directed, however, to the idea of a carcinogenic personality, often said to be characterized by gross self-devaluation, feelings of helplessness and hopelessness, and the tendency to approach environmental demands in a passive, dependent manner. Examples of other illness-prone personalities cited in the literature include the arthritic personality, the anxious–reactive personality, and the disease-prone personality. An illness-resistant personality, called the "hardy personality," has received attention as well. The chief characteristics of this personality are a sense of control regarding issues in one's life, a tendency to see life demands as challenges rather than stressors, and commitment to one's endeavors because they hold meaning for the person. Recently, optimism also has been viewed as a personality attribute that buffers stress and prevents illness (Seligman, 1990, 1998).

Emotional Expression

Recently, researchers have attempted to determine to what extent personality variables are related to illness. The research question has taken one of two forms: (1) Is there a relationship between specific personality variables and specific illnesses, or (2) Is there a predisposition toward illness in general from the possession of certain personality variables? In a meta-analytic review of 101 studies purporting to investigate the effects of strangulated emotions on vulnerability to illness, Howard Friedman and Stephanie Booth-Keeley (1987) found only weak support for a relationship between specific distressing emotions, such as anxiety, anger, and depression, and specific illnesses, such as asthma, ulcers, arthritis, heart disease, and headaches. However, they found substantial support for a relationship between these distressing emotions and an increased vulnerability to illness in general. Consequently, they considered it appropriate to refer to persons accustomed to strangulating their emotions as having a "disease-prone personality." Hostility and negative affectivity, the tendency to be critical of self and others, in particular have been associated with a variety of illnesses across many studies.

Coping Styles of Differing Personalities

The effects of personality on illness may be mediated by differences in the coping styles adopted by dissimilar personality types. Michael Antoni (1987) found that persons who adopt more passive approaches to distressing events trigger a different set of neurological and endocrine reactions than persons who cope more actively. The helplessness, hyper vigilance, and withdrawal tendencies typical of passive coping are associated with much higher concentrations of cortisol, a stress hormone indicted for its negative effects on immune functioning. It seems that high levels of circulating cortisol sustained over long periods of time kill immune cells and hasten age-related memory loss. Elevated levels of cortisol are frequently found in persons experiencing depression, and chronic depression is associated with higher rates of morbidity and mortality. Thus, passive copers may be conducting chemical warfare against their own bodies.

Locke and Colligan (1986) at Harvard University found the effect of multiple life demands on blood levels of natural killer (NK) immune cells was strongly influenced by the presence or absence of distressing emotions. Medical students who reported high levels of anxiety and/or depression while coping with multiple life demands had diminished NK-cell activity, whereas students facing the same magnitude of life demands but reporting little or no anxiety or depression actually showed higher than normal NK cell activity. Thus, it seems that high demand loads have a watershed effect: Personalities given to experiencing high levels

of anxiety and/or depression experience suppression of immune functioning, while personalities devoid of such tendencies appear to have their immune systems further strengthened.

The field of medicine examining the interface of personality features with illness is referred to as psychoneuroimmunology. We now know that there is a direct link between brain structures and immune factors such as the thymus gland, T-lymphocytes, and macrophages. Moreover, we are now discovering that the chemical messengers that operate most extensively in both brain and immune system are dense in neuroanatomical areas that regulate emotion. The traffic seems to go both ways; that is, the brain produces neurochemicals that stimulate receptor sites on immune cells, and the immune system produces biochemicals that stimulate brain cells. Consequently, it seems likely that patterns of thinking typifying different personalities are likely to have differential effects on immune functioning.

In summary, the role of psychological factors conceptualized as features of personalities as causal or aggravating agents of illness is now universally recognized. There is a growing recognition, however, that personality as a construct may be too broad, with too many overlapping meanings, for optimal use in this context. A more rewarding direction for future research should focus attention on the less amorphous constructs often used in defining personalities.

PERSONNEL EVALUATION

Personnel evaluations are formalized practices that provide information about the job performance of employees. Evaluations serve two general purposes: administrative and developmental. Administrative purposes are served to the extent that the evaluations are used to make personnel decisions about such things as salary increases, job assignments, promotions, and selection for training program participation. Developmental uses serve employees by providing feedback about their performance on the job and information that can guide planning for future career roles.

The development of instruments and practices involves at least three major classes of processes and choices: (1) the specification of the performance criteria, (2) the development of performance evaluation measures, and (3) the choice of evaluators.

Performance Criteria

The quality of any personnel evaluation system depends upon the extent to which the major dimensions of performance on the jobs to be evaluated have been identified. These dimensions must be relevant to successful and unsuccessful performance on the job. For example, if one were evaluating the performance of a bank teller, the dimensions of interpersonal interacting with customers, the ability to balance the drawer at the end of the day, and the ability to "interact" with the central computer through individual terminals might represent some of the dimensions of the job on which evaluations should be made. Collectively, the set of dimensions comprises the criteria. Criteria are identified through job analyses.

Criteria can be classified in many different ways. However, psychologists think in terms of two general classes: objective and subjective. Objective criteria are usually part of records kept on employees and, for the most part, are quite straightforward.

Subjective criteria are usually based in some individual's evaluation of the employee's performance. Subjective criteria can be further divided into trait-related and behaviorally related criteria. Examples of trait-related criterion dimensions are friendliness, honesty, aggressiveness, ambition, helpfulness, and work ethic. Behaviorally referenced criteria may include relationships with customers, accuracy of transactions, and skill in working with the equipment interacting with the central computer.

Psychologists almost always favor the use of objective criteria plus subjective criteria that are behaviorally oriented. However, when the overall evaluation is taken into account and it is necessary to compare employees across a wide variety of different types of jobs, the use of behaviorally based evaluations is more difficult. Also, some critical dimensions of work are subjective by nature; for example, cooperation, customer satisfaction, and teamwork.

Performance Measures

Once the criteria have been identified, the next task is to construct ways in which to measure them. Objective criteria, by their very nature, often have standards for their

measurement. For subjective measures of performance, evaluation scales must be developed. To do so requires constructing scales that are reliable, valid, unbiased, and as free as possible from contamination.

A wide variety of scaling procedures and practices exist for the construction of such scales. The perfect evaluation scale, or even one that clearly stands out above the rest, has eluded experts. However, the inability to identify one best method for all criteria should not imply that there have been no major advances. Critical behaviors identified by job incumbents and scaled as to their importance for effective job performance work well.

Evaluators

Because of the hierarchical nature of most organizations, with the well-accepted control mechanism whereby supervisors are responsible for the work of their subordinates, most performance evaluations are done by employees' immediate supervisors. It is also common for the next higher level of supervision to endorse the evaluations. In spite of this practice, there is no reason to believe that supervisors are in the best position to provide the evaluation. In fact, work with peer ratings—ratings obtained from others at a level parallel to the employee—shows that peers are excellent sources of evaluations and are often better than supervisors. From the standpoint of the quality of the rating, the best generalization is that quality is a function of the evaluator's ability to observe and judge the dimension in question. Since much work today is carried out by teams, performance evaluations called "360-degree feedback" are frequently completed by superiors, peers, and subordinates. These evaluations are primarily to help employees see how others perceive them rather than for administrative purposes (e.g., raises, promotions, etc.).

Process Concerns

Until the mid-1970s, psychologists working in the area of performance appraisal concentrated almost all of their efforts on the development of performance rating scales and the procedures for using these scales. It was assumed that evaluators had well-formed notions about performance and that all that was necessary was to develop rating scales that would express the raters' judgments accurately. Recently, psychologists have recognized that it is not that simple. Thus, the process of performance appraisal has received much attention. There is now a widespread belief that improvements that can be accomplished through scale construction alone very likely have been reached. It is now time to turn attention to the evaluation process as a whole.

One of the most important aspects of this process was the recognition that the evaluator is faced with a person-perception problem that requires the perception, memory, and recall of events related to employees. From this perspective, it is necessary to understand how people perceive others, how they retrieve from memory information about others, how the performance evaluation procedure for an organization requires them to record their evaluation, and the use(s) to which the ratings will be put.

Finally, in addition to looking at the evaluator, more attention must be paid to the characteristics of the performance setting. Although performance evaluations are of the utmost importance to the psychologists who develop evaluation systems, to the line manager with many other responsibilities, the appraisal process is just another task that must be completed by a certain deadline. Thus, more attention must be paid to the situational conditions in which appraisals take place, to establish conditions that increase the probability of accurate evaluations. Again, the recent trend is to be more cognizant of the situational constraints and to attempt to deal with the personnel evaluation systems and the context as parts of the nature of the performance itself.

PHENYLALANINE

Phenylalanine

Phenylalanine is an essential hydrophobic aromatic amino acid. The term *essential* in this context means that the amino acid cannot be synthesized endogenously and must be obtained through diet. A common amino acid in proteins, phenylalanine is the immediate precursor of tyrosine, a nonessential amino acid from which catecholamine neurotransmitters are synthesized.

Phenylalanine Metabolism

Phenylalanine not used in protein synthesis is oxidized to tyrosine by the enzyme phenylalanine hydroxylase (Figure 1). This reaction requires a cofactor, tetrahydrobiopterin (BH_4), which is synthesized de novo from guanosine triphosphate. In the reaction, BH_4 is converted to quinonoid dihydrobiopterin, which is reduced back to BH_4 by dihydropteridine reductase. This recycling pathway serves the important function of maintaining the BH_4 cofactor.

Hyperphenylalaninemia

Hyperphenylalaninemias are inborn disorders of phenylalanine metabolism. Normally, about 25% of phenylalanine is used for protein synthesis and the remaining 75% is converted to tyrosine. Hydroxylation of phenylalanine is the principal pathway for phenylalanine runout from body flu-

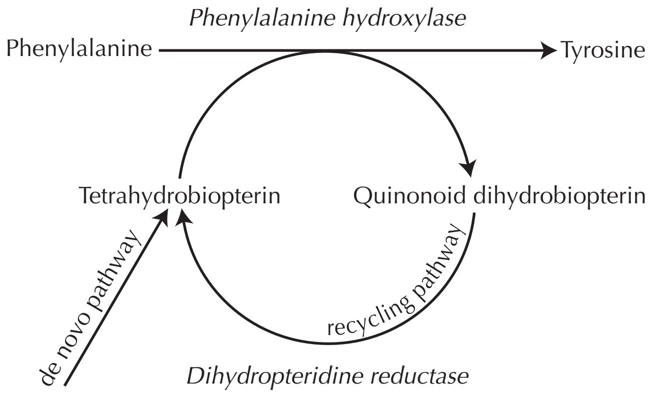

Figure 1. Phenylalanine metabolism. Enzymes are in italicized type.

ids. If this process is impaired, continued input of phenylananine from diet and endogenous sources (i.e., peptide turnover) causes the concentration of phenylalanine in plasma to rise. Impairment of hydroxylation can result from a defect in phenylalanine hydroxylase or, less frequently, in one of the enzymes involved in BH_4 synthesis or recycling. Phenylketonuria (PKU) is a type of hyperphenylalaninemia that is defined on the basis of plasma phenylalanine concentration. When plasma phenylalanine is above an arbitrary threshold (often 16.5 mg/dl) the condition is called PKU. Unfortunately, wide variation exists in the threshold that is employed, leading to differences in clinical practice and incidence estimates. Conditions associated with an elevation of phenylalanine that is below the threshold for PKU are called non-PKU hyperphenylalaninemias.

Clinical Manifestation

Marked elevation of phenylalanine is associated with clinical manifestations most notably involving the central nervous system. Untreated or late-treated PKU usually results in a host of neurologic sequelae including severe mental retardation, seizures, and behavioral (e.g., self-mutilation, aggression, and hyperactivity) and psychiatric (e.g., depression and mania) disorders. A consistent neuropathologic finding is abnormalities in cerebral white matter revealed by magnetic resonance imaging. Persons with non-PKU hyperphenylalaninemia typically have fewer and less severe manifestations.

Recent research has elucidated the relation between genotype and clinical manifestations in the hyperphenylalaninemias. These disorders have an autosomal recessive mode of inheritance. More that 400 distinct mutations of the gene that encodes phenylalanine hydroxylase (located on chromosome 12) have been identified. Severity of the genetic mutation of both alleles correlates with severity of the biochemical and cognitive phenotypes. The presence of a mild mutation on one allele is protective. Intelligence quotient scores tend to be lower when the mutation on both alleles is severe than when one is severe and the other mild. Nevertheless, there is wide variation of IQ within genotype groups due to other influences, such as inherited intellectual disposition and the timing, effectiveness, and duration of treatment.

Aberrant behavior in PKU may be related to neurotransmitter deficiencies. Concentrations of dopamine and serotonin in cerebrospinal fluid have been found to be reduced in persons with hyperphenylalaninemia, and both of these neurotransmitters have been implicated in deviant behaviors that often occur in untreated PKU. The cause of the neurotransmitter deficit is not established, though reduced synthesis is implicated. Two possible bases for reduced synthesis are (1) decreased transport of precursor amino acids to sites of neurotransmitter synthesis due to competition with phenylalanine for transporters; and (2) diminished activity of hydroxylase enzymes. Although in PKU phenylalanine hydroxylase is usually defective, this alone does not appear to reduce catecholamine synthesis, because in the absence of phenylalanine hydroxylase activity tyrosine becomes an essential amino acid and its intake in diet is normally adequate. However, in hyperphenylalaninemias caused by impaired BH_4 synthesis or recycling, activities of tyrosine, tryptophan, and phenylalanine hydroxylase are all diminished because all three enzymes require the BH_4 cofactor. Reduction in tyrosine and tryptophan hydroxylation does interfere with neurotransmitter synthesis.

Treatment

Nervous system damage in PKU is thought to result from phenylalanine toxicity. Recent evidence indicates that the concentration of phenylalanine in the brain is a more important indicator of neurologic risk than the concentration in the blood. Dietary restriction of phenylalanine shortly after birth lowers plasma and brain phenylalanine and prevents major neurologic sequelae. Because early detection and treatment are essential, screening for PKU at birth is now routine in most developed nations. In the past it has been customary to ease dietary restrictions in school-age children on the assumption that the brain is less vulnerable at this time. However, mounting evidence that this practice is associated with behavioral, cognitive, and neurologic deterioration indicates a need to maintain the restricted diet into adolescence or longer. There is evidence that some neurotoxic effects of phenylalanine in persons who were treated early but later removed from diet and in persons not treated early are reversible to some extent by late initiation of a phenylalanine-restricted diet.

Treatment of disorders of BH_4 synthesis or recycling requires additional measures. In these disorders, catecholamine and serotonin neurotransmitters are deficient even when phenylalanine is controlled, because BH_4 is a re-

quired cofactor for tyrosine and tryptophan hydroxylase. Treatment with L-dopa and 5-hydroxytryptophan, the immediate precursors of dopamine and serotonin, is necessary to correct deficiencies in these neurotransmitters.

Maternal PKU

Children who do not have hyperphenylalaninemia but who are born to affected women who do not maintain dietary restrictions during pregnancy can suffer various teratogenic effects of phenylalanine, including mental retardation, microcephaly, growth retardation, and heart malformations. This condition is called maternal PKU. Control of blood phenylalanine by maternal dietary restriction from conception to birth is associated with improved fetal outcome. There is a strong inverse relationship between maternal phenylalanine levels above 6 mg/dl during pregnancy and IQ of the child. Fetal vulnerability to phenylalanine is greatest during the first trimester. About 90% of infants born to PKU mothers not maintained on the phenylalanine-restricted diet during pregnancy are severely affected. It has been estimated that without proper maternal control of phenylalanine, the benefits of infant screening and treatment for PKU will be erased in one generation.

PHEROMONES

Pheromones are chemical signals that pass between organisms of the same species and have inherent communicatory function. Pheromones likely originated in the earliest life forms and continue to serve as the primary means of communication in many species, including most terrestrial and aquatic invertebrates, fishes, and many mammals. Pheromones are notorious for their potency and specificity, features that are generally attributed to specialized components of the olfactory system. Diverse biochemicals can have pheromonal function; however, with the exception of insects, the pheromones of few animals have been definitively identified. Because pheromones are frequently mixtures of common compounds and can have a variety of functions, the defining characteristic of pheromones lies not in their chemical identity or specific function, but in the ability of conspecifics to recognize them.

Pheromones are most appropriately characterized by their actions, which are generally species-specific, and can include behavioral (“releaser”) and/or physiological (“primer”) effects. Best known are releaser effects, which are associated with reproduction, aggregation, territory marking/recognition, or alarm. Many terrestrial, aquatic, and aerial species locate and select mates using potent reproductive pheromones. For example, male moths are attracted to the odor of females located hundreds of meters away, male dogs respond to the scent of bitches in heat nearly a kilometer upwind, and male goldfish detect female sex pheromones at concentrations as low as 1 gram in 3 billion liters of water. Aggregation pheromones bring individuals of the same species together and are employed by unicellular slime molds to form fruiting bodies, by migrating lamprey to locate spawning rivers containing the odor of larval lamprey, and by swarming insects. In contrast, terrestrial mammals such as antelopes and badgers use territorial pheromones to maintain spacing. Terrestrial and aquatic organisms commonly use alarm pheromones such as “Schreckstoff,” which is released from the skin of injured fish. The potency and specificity of releaser pheromones has led to their application in the management of nuisance species.

Many pheromones with largely physiological (primer) effects are also known. In rodents, juvenile females advance puberty in response to male urinary odor (the Vandenburgh effect) and delay puberty in response to female urinary odor, whereas pregnant females abort preimplantation embryos in response to unfamiliar male odor (the Bruce effect). In goldfish and carp, males exhibit rapid endocrine responses to female steroidal sex pheromones that also affect behavior, demonstrating the multifunctionality of some pheromones.

The chemical nature of pheromones varies enormously and is much better understood in insects than in vertebrates. Pheromones are often compounds that originally served other, related functions. In the goldfish and its relatives, identified sex pheromones are unspecialized hormonal products whose release and detection largely benefits the receivers. However, in other cases, pheromone “donors” have evolved specialized abilities to produce and release pheromonal products, apparently because they derive benefit from doing so. Thus, many insects and ungulates control the release of molecular blends produced in quantity by special glands. Sex pheromones of noctuid moths are precise species-specific mixtures of up to seven fatty acids and related acetates, aldehydes, and alcohols. Among mammals, most pheromones appear to be complex mixtures hidden within the body odor of the donor that benefit both the donor and receiver of the signal, a condition that some mammalian chemical ecologists equate with the use of the term.

Although a range of chemicals can serve as pheromones, the chemical characteristics of pheromones are often related to ecological context. Alarm and sex pheromones of terrestrial insects are often small, volatile compounds that spread and fade quickly. Interestingly, elephants use some of the same volatiles as sex pheromones for close-range communication as moths. Water presents a different challenge, and fish often use relatively small, soluble conjugated steroids as pheromones. In contrast, hyenas mark territories with large molecules that last for months in the

hot sun, and rodents mark with long-lived odors that bind with a stable protein, the major urinary protein (MUP).

Where understood, olfactory processing of pheromonal information in invertebrates and vertebrates exhibits striking similarities that include the presence of sexually dimorphic components specialized for pheromonal function. Pheromones are detected by specific sensory hairs located on antennae of invertebrates such as moths and lobsters, while a specific type of receptor neuron, the microvillous cell, appears to mediate responses to pheromones in vertebrates. Invertebrates and vertebrates also exhibit similar organization of the neurons that process pheromonal information. In male moths, axons from receptor neurons project to a specialized subset of glomeruli, the macroglomerular complex (MGC) located in their olfactory lobe. Connections among MGC glomeruli enable males to discriminate pheromone mixtures and adjust flight maneuvers. Pheromone receptor neurons of vertebrates also appear to project to specific glomeruli which in fish are found in medial regions of the olfactory bulb. In terrestrial vertebrates the situation is complex because, with the exception of primates and humans, tetrapods have a dual olfactory system comprised of a main olfactory epithelium and vomeronasal organ (VNO). The latter is located in the roof of the mouth. Although both systems can mediate pheromone responses, the VNO appears to be the primary system for discriminating pheromones because naive rodents that lack a VNO do not respond to some pheromones.

Although responsiveness to pheromones is typically instinctual, some responses can be learned. Honeybees learn to recognize hydrocarbon mixtures on the bodies of nest mates, whom they allow to enter the nest. Young mice imprint on their parent's odor (which appears to be associated with the Major Histocompatability Complex [MHC]) and later avoid it when choosing mates. Similarly, the Bruce effect depends on the ability of female mice to learn male odor during mating.

There are suggestions that human mate choice is influenced by odors associated with the MHC, as people choose partners with different MHC profiles. Pheromones also appear to mediate the menstrual synchrony of women living in close proximity, although the active compounds are unknown. With the advent of molecular techniques, understanding of pheromone identity and function is expected to advance rapidly.

PHILOSOPHY OF PSYCHOTHERAPY

Psychotherapy is often considered to be an applied science consisting of a compendium of techniques or approaches validated by empirical research. Alternately, it is viewed as an art form requiring a creative, intuitive, and individualistic approach to clients and their problems. However, psychotherapy can also be regarded as influenced in a fundamental way by broader, philosophical underpinnings that transcend its scientific, human engineering, or artistic dimensions. Examples of some of these domains are: (1) our possessing a priori categories of understanding that are part of therapeutic work, such as certain assumptions about reality, and underlying narrative structures; (2) the inevitability of value-laden issues in therapy; and (3) the presence of societal and cultural influences on the practice of psychotherapy, as well as the effect of psychotherapy on the terms in which people in our society view themselves (Messer & Woolfolk, 1998; Woolfolk, 1998). We will take up each of these three areas in turn.

A Priori Categories of Understanding

Every intellectual endeavor has a starting point that is prior to empirical investigation. Without the conceptual categories that are prior to experience we could not organize the world into objects and events. When we look at the world, we do so through particular lenses or conceptual schemes that influence what we see. Philosophical analysis is a tool for making the properties of these lenses explicit, helping us to understand the concepts that underlie our thinking.

One aspect of the philosophical and cultural *a priori* is referred to by contemporary philosophers as "the Background." It contains the taken-for-granted knowledge and norms that are implicit in our practical and theoretical activities. Consider, as an example of the Background, the contrasting narrative themes underlying different forms of treatment, which often go unrecognized. One typology of narratives describes four such "visions" or viewpoints: romantic, tragic, ironic, and comic (Frye, 1957). From the *romantic viewpoint,* life is an adventure or quest, a drama of

the triumph of good over evil, virtue over vice, and light over darkness. It idealizes individuality and authentic self-expression. The romantic vision underpins humanistic approaches to psychotherapy, which stress the value and possibilities of spontaneity, authenticity, and creativity. The *ironic vision,* by contrast, encompasses an attitude of detachment and suspicion, of keeping things in perspective, and of recognizing the fundamental ambiguity and mystery of every issue that life presents. Whereas behavioral and cognitive therapists tend to take client complaints at face value, and humanistic therapists accept most client feelings as authentic expression, psychoanalytic therapists are more likely to look for hidden meanings, paradoxes, and contradictions. This puts them more squarely in the ironic mode.

The *tragic vision* is an acceptance of the limitations in life—not all is possible, not all is redeemable, not all potentialities are realizable. The clock cannot be turned back, death cannot be avoided, human nature cannot be radically perfected. Many aspects of psychoanalysis fall within the tragic vision. People are determined by events of their early childhood, which are subject to repression and beyond their conscious purview. The outcome of psychoanalytic treatment is not unalloyed happiness or all obstacles overcome, but rather the fuller recognition and acceptance of what one's struggles are about, and of the conditions and limitations of life. By contrast, within the *comic vision* the direction of events is from bad to better or even best. Obstacles and struggles are ultimately overcome. Harmony and unity, progress and happiness prevail. Cognitive-behavioral therapy holds out the promise of finding greater happiness through the application of scientific principles of healing, while humanistic approaches emphasize the substantial possibility for gratification. These underlying visions profoundly affect both the process and desired outcomes of these different forms of treatment.

Psychotherapy and Values

Virtually all of the innovators who made significant contributions to psychotherapy, such as Freud, Rogers, Wolpe, Perls, and Beck, considered themselves to be discoverers of morally neutral, scientific knowledge, and viewed psychotherapy as an objective application of that knowledge to the goal of psychological health. By contrast, philosophical analysis helps us to see how values often establish, albeit covertly, the criteria for intervention; influence patterns of therapeutic exploration; and promote standards for client conduct. For example, a middle-aged man comes to a therapist announcing that he is considering leaving his wife for a much younger, recently married woman, and wants help making the decision. A therapist operating within the values of liberal, secular individualism would stress the happiness and contentment of the individual above all else and above all others, encouraging him to explore the issue in these self-directed (some might say "selfish") terms. One who holds to communitarian values might be more inclined to address how the client's decision to leave his wife will cause others to suffer, such as spouses, children, and other family members. Yet another therapist, hewing to religious values such as the sanctity of marriage, might emphasize the psychological and moral consequences of breaking marital vows. Despite claims to the contrary, there is no value-free psychotherapy.

The Intersection of Psychotherapy with Societal and Cultural Worldviews

The institution of psychotherapy is a significant source of, and influence on, contemporary customs, values, and worldviews, and is constantly incorporating them in its purview (Messer & Wachtel, 1997; Woolfolk, 1998). For example, all societies need mechanisms that establish what behavior is to be promoted and what is to be proscribed. Although we most often think of clinicians as healers, they also function as agents of social control. The clinician is granted responsibility for many bizarre, incapable, or destructive individuals whom the rest of society will not or cannot tolerate.

Psychotherapy and its related theory and language are also cultural phenomena that have affected how people think about themselves. For example, lay people refer to Freudian slips, defenses, guilt complexes, conditioned responses, existential angst, identity crises, or discovering their true selves—all terms related to the activity of psychotherapy. Similarly, when they explain their problems in terms of childhood occurrences such as parental neglect or harsh criticism, repressed memories, or learned associations they demonstrate that psychotherapy is far more than a scientific or technical endeavor. Its language constitutes the very belief systems that people employ to make sense out of their lives.

PHINEAS GAGE

On September 13, 1998, a group of brain scientists, including neurologists, neuropsychologists, and neurosurgeons, gathered in the hamlet of Cavendish, Vermont, to commemorate a bizarre anniversary. It was the 150th anniversary of an accident in which a young man named Phineas Gage suffered a brain injury when an iron bar was shot through the front part of his head. The accident itself was remarkable enough—immediately afterward, despite a gruesome wound to the front of his head and brain, Gage was conscious, alert, and talkative, and it seemed rather a miracle that he had even survived. But what followed over the next few decades, and then over the many years since, is what put Cavendish, Vermont, on the scientific map, and the reason why scientists traveled from around the world that late summer day in 1998 to commemorate the anniversary (see Macmillan, 2000).

On September 13, 1848, Phineas Gage was laboring with coworkers to blast a bed for railroad tracks through the rugged, rocky terrain of southern Vermont. While setting an explosive, Gage prematurely triggered an explosion with his tamping iron. The iron was propelled through the front part of his head, entering his left cheek just under the eye, piercing the frontal lobes of his brain, and exiting through the top front part of his head. In light of the comparatively primitive state of medicine in the mid-nineteenth century, Gage's medical recovery was nothing short of astonishing—he survived this massive onslaught with normal intelligence, memory, speech, sensation, and movement. Following this surprising recovery, however, Gage displayed a profound change in personality and social conduct that established him as a landmark case in the history of neuroscience. Before the accident, he had been responsible, socially well-adapted, and well-liked by peers and supervisors. Afterwards, Gage proved to be irresponsible and untrustworthy, irreverent and capricious, with markedly unreliable behavior and little regard for social convention; in short, he was "no longer Gage."

Gage's physician, John Harlow, speculated (very accurately, as it turned out) that there was a causative relationship between the damage to the front part of Gage's brain and the profound change in his personality and social conduct (Bigelow, 1850; Harlow, 1868). Harlow's observations, although never fully appreciated by his contemporaries, hinted at a conclusion that was both radical and prescient: there are structures in the front part of the human brain that are dedicated to the planning and execution of personally and socially adaptive behavior, and to the aspect of reasoning known as rationality. Case reports published over the first several decades of the twentieth century supported Harlow's contention, and modern investigations have documented that the prefrontal region is crucial for moral reasoning, social conduct, planning, and decision-making (Damasio & Anderson, 2003; Tranel, 2002). Moreover, when this region is damaged early in life, the development of social and moral reasoning may be permanently precluded (Anderson, Bechara, Damasio, Tranel, & Damasio, 1999; Anderson, Damasio, Tranel, & Damasio, 2000).

Using tools of modern neuroscience, scientists have performed a detailed reconstruction of the injury to Gage's brain (Damasio, Grabowski, Frank, Galaburda, & Damasio, 1994). From measurements of Gage's skull and the tamping iron (which are part of the Warren Anatomical Medical Museum at Harvard University), scientists were able to reproduce the precise path the tamping iron traversed through Gage's brain. (The skull and iron, which were on display at the 150th anniversary celebration, are remarkably well preserved to this day.) This reconstruction confirmed that the damage included the left and right prefrontal regions, anterior to structures required for motor behavior and speech, in precisely the location that modern studies have highlighted as the key neural underpinning of social conduct and rational decision making.

The importance of the case of Phineas Gage can be more fully appreciated when one considers just how difficult it has been to unravel the cognitive and behavioral functions that are subserved by the prefrontal region of the human brain. The prefrontal sector, situated anterior to the motor/premotor cortices and superior to the sylvian fissure, comprises an enormous expanse of the brain, forming nearly half of the entire cerebral mantle. In humans in particular, this region has expanded disproportionately. Throughout the history of neuropsychology, the psychological capacities associated with the prefrontal region have remained enigmatic and elusive. Beginning with the observations of Phineas Gage, however, the special significance of this region began to be appreciated.

Following on Harlow's prescient writings regarding Gage, other investigators have called attention to the oftentimes bizarre development of abnormal social behavior that can follow prefrontal brain injury (e.g., Eslinger & Damasio, 1985; Stuss & Benson, 1986). The patients have a number of features in common (see Damasio & Anderson, 2003): inability to organize future activity and hold gainful employment, diminished capacity to respond to punishment, a tendency to present an unrealistically favorable view of themselves, and a tendency to display inappropriate emotional reactions. Making this profile especially puzzling is the fact that most of these patients, like Gage, retain normal intelligence, language, memory, and perception. Other scientists have called attention to the striking characteristics of patients with prefrontal lobe brain injury, especially damage to the ventral and lower mesial portions of this region (the "ventromedial prefrontal" sector). Blumer and Benson (1975) noted that the patients displayed a personality profile (which the authors termed "pseudo-psychopathic") featured by puerility, a jocular attitude, sexually disinhibited humor, inappropriate and near-total self-indulgence, and complete lack of concern for others. Stuss and Benson (1986) emphasized that the patients demonstrated a remarkable lack of empathy and general lack of concern about others.

The patients showed callous unconcern, boastfulness, and unrestrained and tactless behavior. Other descriptors included impulsiveness, facetiousness, and diminished anxiety and concern for the future.

It is interesting to note that this personality profile is strikingly similar to that characterized in clinical psychology and psychiatry as psychopathic (or sociopathic) (American Psychiatric Association, 1994). In fact, this condition has been dubbed "acquired sociopathy," to emphasize the fact that prefrontal injured patients often have personality manifestations that are quite reminiscent of those associated with sociopathy (Barrash, Tranel, & Anderson, 2000; Tranel, 1994). The qualifier "acquired" signifies that in the brain-damaged patients, the condition follows the onset of brain injury, and occurs in persons whose personalities and social conduct were previously normal (as in the case of Phineas Gage). Patients with acquired sociopathy have a proclivity to engage in decisions and behaviors that have negative consequences for their well-being. They repeatedly select courses of action that are not in their best interest in the long run, making poor decisions about interpersonal relationships, occupational endeavors, and finances. In short, the patients act as though they have lost the ability to ponder different courses of action and then select the option that promises the best blend of short- and long-term benefit.

As it turned out, the misadventures of Phineas Gage provided crucial early clues about the importance of the prefrontal sector of the brain for social behavior, reasoning and decision-making, and what can generally be called "personality." Phineas Gage's accident was bizarre, to be sure, but its important place in scientific history is firmly secure.

PHONEMES

Linguistic analyses have traditionally represented the form of speech in terms of *phonemes.* The word *cat,* for instance, can be represented by a sequence of three phonemes: /k/, /æ/, and /t/. Changes in the phonemic construction of a word will result in a different word, or a nonsense word. For example, reordering the phonemes in *cat* can produce other words, such as *act* (/ækt/) or *tack* (/tæk/), whereas replacing the /k/ with a /p/ results in a new word, *pat.* Words like *cat* and *pat* that differ on the identity of a single phoneme are referred to as minimal pairs, and provide a useful source of evidence for defining the phonemic inventory for a language. In an alphabetic language such as English, the phonemic nature of speech is made explicit by the close correspondence between letters and the phonemes they represent. Logographic languages (e.g., Chinese) do not share this correspondence; instead, characters are used to represent whole words.

A further division of speech sounds is possible, into subphonemic units called *phonetic features.* The representation of a phoneme consists of a set of phonetic features, which capture the similarities and differences between groups of phonemes. For example, the difference between

the phonemes /t/ and /k/ is largely due to the difference in the place of closure created by the tongue touching the roof of the mouth. The same contrast is found between /d/ and /g/, and between /n/ and /ŋ/ (the final phoneme in "ring"). This contrast can be represented by one or more places of articulation features.

It is important to realize that the abstract notion of a phoneme obscures a great deal of variation in the form of speech. The context in which a phoneme is uttered has a strong effect on the way in which it is articulated, and this results in a wide variation of acoustic forms all being termed the same phoneme. Similarly, the discrete sequences of symbols in a phonemic transcription do not properly represent the temporal structure of the speech waveform, in which information about different phonemes is spread across time or overlapping. A critical issue in the psychological study of speech is whether mental representations of speech reflect the diversity and detail of the speech waveform or the abstractness and simplicity of the phonemic transcription.

Phonemes in Speech Perception

It is clear that some aspects of the organization of speech sounds in perception correspond to phonemic categories. It is possible to create artificial continua using recorded speech or a speech synthesizer in which the extremes correspond to two typical phonemes. Typically adults will show categorical perception of these continua; that is, they will find it difficult to discriminate between two sounds on a continuum that would be classed as the same phoneme, but relatively easy to discriminate between two sounds that cross a phoneme boundary. Infants as young as a month old show similar discontinuities in their perception of these continua. In fact, it seems that early on in development, infants are able to discriminate between speech sounds that are allophonic in their language (i.e., phonetically distinct members of the same phoneme category) but are different phonemes in other languages. This ability is lost in the first year of life, as the infant becomes familiar with the phonemes of his or her native language.

A possible conclusion to be drawn from these studies of infant speech perception is that people are born with an innate universal phonemic inventory, from which the contrasts relevant to the child's native language are consolidated. However, various nonhuman species, such as chinchillas and macaque monkeys, have also shown categorical perception of some phonemic contrasts. So what is innate may in fact be more physical aspects of the auditory system, which provide a basis for discrimination between some sounds but not others. By this view, the phonemic systems of languages have evolved in order to take advantage of these abilities and deficits.

Although categorical perception of phonemes is found from infancy, it is less clear how aware people are of these units. Alphabetic languages lend themselves to a phonemic decomposition of speech by the literate adult. This makes the conscious manipulation and decomposition of speech (such as deciding what the initial phoneme of "spin" might be) a relatively simple task. However, for verbally proficient illiterate adults and speakers of nonalphabetic languages this is not the case. It seems that the existence of the phoneme as a unit at a conscious level relies on more or less explicit teaching through learning to read alphabetic scripts.

The phoneme has been proposed as the initial unit of classification in speech perception at a subconscious level. The assumption is that words are identified by comparison between this representation and stored phonemic representations of words. However, the lack of context-invariant characteristics for many phonemes has weakened this proposal, and other models have been suggested in which speech is mapped onto larger units (e.g., the syllable) or smaller units (e.g., acoustic features) before searching the lexicon for a matching word. The matching process between the speech waveform and the mental lexicon has also proved to be sensitive to a wide range of subtle changes in the form of words, suggesting that very little acoustic detail is discarded during the recognition of spoken words. Currently, there is no consensus on the importance of the phoneme unit in spoken-word recognition.

Phonemes in Speech Production

There is greater agreement among psycholinguists about the role of the phoneme in speech production. Most current models assume that words are selected according to the conceptual requirements of the speaker, and then the phonemes making up that word are selected for articulation, possibly with reference to a store of known syllables. Originally, these models relied on data from speech errors in order to define the units involved in production. Errors are not common in natural speech, but when they do occur many of them involve substitutions, anticipations, or perseverations of phonemes. In the case of Spoonerisms, the substitution results in sequences that correspond to real words (e.g., "you have hissed all the mystery lectures" instead of "you have missed all the history lectures"). These phonemic errors will often preserve the syllabic information related to the phonemes involved, such that syllable-initial phonemes are unlikely to end up at the end of another syllable. Phonemic similarity and whether or not the change would produce a real word are also influential factors in defining the likelihood of a speech error. In the last few years these error data have been augmented by more sophisticated techniques that allow error-free speech production to be studied. These techniques have been particularly useful in mapping out the time course of the various processes in speech production.

PHONETICS

Phonetics, often defined as the scientific study of speech sounds, encompasses three primary areas of interest: (1) speech sound production, (2) acoustic transmission of speech sounds, and (3) speech sound reception. The field of phonetics is interdisciplinary and draws upon the natural sciences (anatomy, physiology, physics), the social and behavioral sciences (psychology, sociology, anthropology, linguistics), and engineering. In turn, the principles of phonetics are applied in such diverse fields as education (foreign language pedagogy, reading), health care and rehabilitation (speech-language pathology), the humanities (vocal music), and forensics. The phonetic sciences also impact industry; telecommunications, speech recognition software packages, and synthetic speech applications incorporate phonetic principles and are widely available.

A basic goal of phonetics has been to develop reliable and valid conventions for describing speech production. In practice, this is accomplished using two complementary approaches: impressionistic phonetic transcription and instrumental measurement. These procedures are designed to allow one to document speech patterns regardless of the language that is being spoken.

Phonetic Transcription

Several phonetic alphabets have been developed; however, the International Phonetic Alphabet (IPA) is perhaps the best known and most widely used system. The IPA, like the familiar Latin alphabet, uses symbols to represent different speech sounds; however, the IPA differs from traditional orthography in both scope and consistency.

Whereas the Latin alphabet has only 26 letters, the current IPA consists of more than 100 symbols representing the sounds of the world's languages. In addition, IPA symbols have been developed to describe suprasegmental or prosodic aspects of speech (e.g., stress, duration, tone). Diacritic symbols exist for documenting nuances of speech sound production. Thus, the scope of the IPA is much broader than traditional orthography.

The IPA also is more consistent in its representation of speech sounds. In traditional orthography, the relationship between sound and symbol may vary. For example, the letter "c" is pronounced as [s] in some words (e.g., "city") and as [k] in others (e.g., "cap"). A basic principle of the IPA is that each phonetic symbol will represent one (and only one) distinctive sound; accordingly, each sound will be represented consistently by one (and only one) symbol.

The IPA is well suited for the description of individual differences in speaking patterns. It is often used to document dialectal differences, speech performance errors (i.e., slips of the tongue), foreign accent, as well as disordered speech. Extensions to the IPA have been developed to document sounds that are produced only by speakers with disordered speech. Impressionistic phonetic transcription provides valuable information regarding speech production; however, it requires much practice to develop the skill and even experts may disagree on the most appropriate way to render a given production.

Instrumental Measurement

Phoneticians often use specialized laboratory equipment and software to study acoustic and articulatory aspects of speech production. Traditionally, tape-recorded speech signals were examined using an oscilloscope, sound spectrograph, and other instruments to complete acoustic measurements. The spectrograph, for example, allowed the phonetician to examine changes in the frequency and intensity characteristics of conversational speech. Today, advances in processing speed and signal storage have made it commonplace for phoneticians to capture speech signals using microcomputers. The signal may then be retrieved and properties such as frequency, intensity, and duration can be measured. The widespread availability of digital signal processing has stimulated the development of high-quality—yet low-cost—speech analysis software packages.

There also have been many advances in the measurement of articulation. For example, electropalatography (EPG) allows one to examine tongue-to-palate contact during running speech. Another procedure, electromagnetic articulography (EMA), provides a noninvasive means of measuring and graphing movements of the speech organs. Such objective instrumental analyses may be used to quantify speech movements and to refine phonetic transcriptions. In addition, speech instrumentation has been used to provide biofeedback to improve the pronunciation of second language learners and to diagnose and treat speech disorders in children and adults.

The field of phonetics is diverse, and many branches within the field have been described. For example, *experimental phonetics* has been distinguished from *descriptive phonetics.* Experimental phonetics seeks to examine the impact of various conditions upon speech production or perception under controlled conditions, whereas descriptive phonetics seeks to document naturally occurring speech production patterns, often for purposes of classification or to track changes in speech patterns over time (the latter is sometimes referred to as *historical* or *diachronic phonetics*). Likewise, *theoretical phonetics* has been distinguished from *applied phonetics* (also known as *practical phonetics*).

The term *articulatory phonetics* denotes the branch of phonetics devoted to studying the relationship between speech anatomy and sound production. The branch that is concerned with the study of the physics of speech transmission is known as *acoustic phonetics.* A third branch, *auditory phonetics* or *perceptual phonetics,* emphasizes the study of speech sound reception and the factors that influence it. Other specializations have been identified in the field of phonetics, including *linguistic phonetics* (which provides insight into the nature of human language systems),

comparative phonetics (which discerns similarities and differences among sounds of different languages, often for educational purposes), *clinical phonetics* (which applies phonetics to the study, diagnosis, and treatment of human communication disorders), *neurophonetics* (which emphasizes the relationship between neurology and speech production/perception), and *forensic phonetics* (which applies phonetics to crime investigations such as the use of speech patterns to help identify a perpetrator's identity).

Phoneticians have catalogued the sounds of many of the world's languages. Although universal tendencies have been identified, there is considerable variability in the number and types of sounds that are used by speakers of different languages. Speakers of the Hawaiian language, for example, produce few (approximately 13) distinct sounds, and some languages use even fewer sounds. American English, in contrast, has more than 40 distinct sounds. Speakers of !Xung (an African language) reportedly produce more than 140 distinctive sounds—more than any other known language. The field of phonetics continues to evolve as a scientific discipline to provide insight into the most human of behaviors—speech.

PHOTORECEPTORS

Photoreceptors are specialized receptors for translating the absorption of light into electrical signals, which are the language of the nervous system. Photoreceptors have reached the physical limits of light detection and can register the absorption of a single light quantum. On the other hand, our eye can adapt its sensitivity to light levels 10^9-fold higher.

The interior surface of the vertebrate eye is covered by the retina, which is part of the central nervous system. It harbors the photoreceptors as well as neurons that process the information before it is relayed to the brain by the ganglion cells. The retina is inverted, that is, the light falls through all retinal layers before it reaches the photoreceptors (Figure 1). Two types of photoreceptors can be distinguished: the rods (120 million in a human eye) for vision in dim light, and the cones (6 million per eye) for daylight and for color vision. Photoreceptors each have a cell body, an axon that forms synapses with other neurons, and an inner segment that contains the machinery for routine cellular metabolism. Photoelectrical transduction takes place in the outer segment, which contains photopigment molecules, all biochemical components for the signal amplification, as well as the ion channels that are needed to generate the electrical response.

Phototransduction

The ion channels in the outer segment are opened by intracellular messenger molecules, cyclic guanosine-monophosphate (cGMP; Yau & Baylor, 1989; Finn, Grunwald, & Yau, 1996). In the dark, the cGMP concentration in the outer segment is high, channels open, and Na^+ and Ca^{2+} ions enter the cell through these open channels, thereby adjusting the membrane voltage to around –35 mV. At this membrane voltage, the photoreceptor releases transmitter molecules at its synapse. The retinal neurons process this information and relay it to the brain, where it is interpreted as "dark."

Rod outer segments contain a stack of flat, hollow membrane compartments, the discs (Figure 2). The photopigment rhodopsin is found in high concentration within the disc membranes (up to 100 million rhodopsin molecules per rod). Rhodopsin consists of a protein part (the opsin), which is inserted into the disc membrane, and a light absorbing part, the aldehyde form of vitamin A, retinal (Figure 2). Retinal can exist in different forms. The folded 11-cis form of retinal is bound within the rhodopsin. Absorption of a light quantum switches the 11-cis retinal to the elongated all-trans form, which induces a conformational change in the rhodopsin molecule—it becomes "activated." Light-

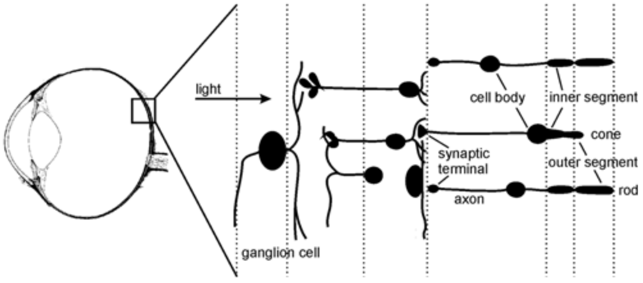

Figure 1. Section through the eye and the retina, showing different retinal cell types.

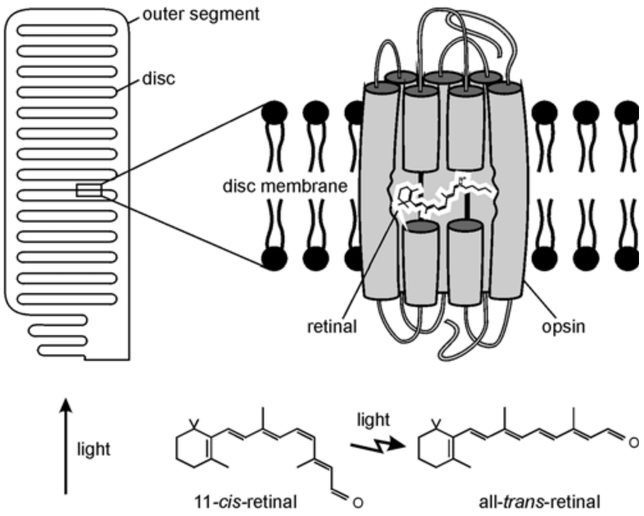

Figure 2. The rod outer segment contains hundreds of discs with millions of rhodopsin molecules.

activated rhodopsin is capable of activating protein molecules called transducin, which in turn activate a third protein class, the phosphodiesterase. The activated phosphodiesterases destroy cGMP molecules, the cGMP concentration falls rapidly, and the ion channels close. As fewer positive ions enter the cell, the membrane voltage becomes more negative and less transmitter is released at the synapse (Yau, 1994). This information is processed further and is interpreted by the brain as "light."

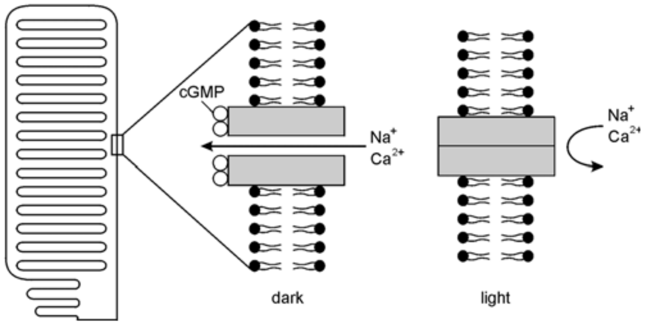

Figure 3. In the dark, ions enter the outer segment through the cGMP-gated channels in the plasmamembrane. Upon illumination, channels close and the influx ceases.

Sensitivity and Adaptation

One light-activated rhodopsin molecule may activate up to 150 transducin molecules, each of which can activate one phosphodiesterase molecule. Each phosphodiesterase can cleave up to 2000 cGMP molecules per second. Due to this high amplification, the absorption of one light quantum leads to the closure of many channels and a measurable change in membrane voltage. With brighter light, more cGMP is destroyed, more channels close and the voltage can reach –70 mV.

Photoreceptor adaptation is only incompletely understood. The internal messenger Ca^{2+} is very important (Kaupp & Koch, 1992). The internal Ca^{2+} concentration is high in the dark, when Ca^{2+} enters through the cGMP-gated channels, but drops rapidly when the channels close upon illumination. Ca^{2+} binding proteins serve as Ca^{2+} sensors and relay the change in Ca^{2+} concentration to their target enzymes in order to adjust their activity. One consequence is the activation of the guanylyl cyclase, which increases cGMP production. Furthermore, the light response becomes truncated. At low Ca^{2+} concentration, light-activated rhodopsin is shut off by the proteins rhodopsin kinase and arrestin, so that fewer tranducin molecules are activated. The gain of the cascade becomes smaller; that is, the cell becomes less sensitive and its operating range increases. Adaptive mechanisms are also postulated in the retinal network; some may follow a circadian rhythm.

Psychophysics

Cones function in a manner similar to that of rods, but are less sensitive. We can distinguish colors because our retina harbors three types of cones whose opsins differ in their sensitivity to light of different wavelengths. Mutations in the cone opsins may result in abnormal color vision. Vision is best in the central retina ("fovea"), where cones are densely packed and the information of each cone is transmitted separately from others to the brain. In the peripheral retina, many photoreceptors converge onto one postsynaptic cell, hence resolution is lower. The fovea contains no rods and is night-blind.

In dark-adapted rods the high signal amplification may need 200 milliseconds to build up the light response, which can last up to a second. But even in light-adapted rods and cones light responses last 15 to 50 ms, thus we cannot resolve more than 60 events per second. Therefore, in our perception, pictures in movies fuse to a continuous motion. In comparison, photoreceptors of many insects would need more than 200 pictures per second for fusion.

PHRENOLOGY

Phrenology, now an outmoded theory of personality, originated with the speculations of the physician-anatomist Franz Joseph Gall (1758–1828). Intrigued by a personal inference that individuals with bulging or prominent eyes had good memories, Gall began to look for personality correlates of other features such as broad foreheads, prominent jaws, and so on. Ultimately, he focused his attention primarily on the brain and skull and founded what he called the new science of craniology. Knowledge of the brain and nervous system at that time was vestigial at best. In consequence, much of Gall's early work on his theory included the development of new techniques of dissection, perfection of the construction of brain and skull models, and the amassing of a unique collection of skulls. The superb quality of this supporting anatomical work gave Gall great

credibility when he first presented his ideas to the medical community.

Gall's basic belief was that mental functions are located in the brain, and that their exercise and perfection would lead to localized brain development. This, in turn, would lead to appropriate enlargement of the related areas of the surrounding skull. Thus, by a very close scrutiny of the skull and its various prominences, one could obtain a detailed, individualized diagnosis of an individual's personal qualities and characteristics. He was thus the first researcher to postulate what has come to be known as localization of brain function—a precursor of modern neuropsychology in which physiological measures of brain and nervous system activity are correlated with psychological observations.

Around 1800, Spurzheim (1776–1823), a pupil of Gall, joined him on a lecture tour to espouse the new science of phrenology (a term never used by Gall). A dynamic and convincing lecturer, Spurzheim changed the emphasis to stress mostly the detection of the presence of positive faculties and their modifiability by means of strategic training. The approach to "reading bumps" became less akin to medical diagnosis and more to quackery and fortune telling. Correspondingly, phrenology lost its popularity and acceptance by medical groups, but simultaneously became popular with the general public.

PHYSICAL ATTRACTIVENESS

Physical attractiveness has been defined as "That which represents one's conception of the ideal in appearance; that which gives the greatest degree of pleasure to the senses" (Hatfield & Sprecher, 1986, p. 4).

Artists, philosophers, and scientists have asked if there are any universal standards of beauty. In the fifth century B.C., for example, the Greek philosopher Aristotle proposed that the Golden Mean, a perfect balance, was a universal ideal.

Aristotle appears to have been right. When social scientists asked people to compare individual faces with average faces, they found people greatly preferred the latter. Researchers assembled photographs of men and women's faces. Then, using video and computer techniques, they generated a series of composite faces. Inevitably, students found the composites to be more appealing than any individual face.

Evolutionary psychologists contend that men and women prefer faces that, in a sense, "have it all"—faces that combine the innocence of childhood with the ripe sexuality of the mature. Early ethnologists discovered that men and women often experience a tender rush of feeling when they view infantile "kewpie doll" faces—faces with huge eyes, tiny noses and mouths, and little chins. Later, sociobiologists discovered that men and women are aroused by faces that possess features associated with maturity, especially lush, adult sexuality (for example, thick hair, dewy skin, and full lips) and mature power (for example, high cheekbones or a firm jaw and chin). Recent evidence suggests that people prefer faces that possess *both* assets: large eyes and small noses, full sexual lips, and strong jaws and chins (see Rhodes & Zebrowitz, 2002). Whether these preferences will turn out to be truly universal is not yet known.

Evidence That People are Biased in Favor of the Physically Attractive

Scientists find that most people, most of the time, are biased in favor of the good-looking. The Greek philosopher Sappho contended that "what is beautiful is good." Today, scientists have come to a fuller understanding of just how, where, when, and why physical appearance is important. There seem to be four steps in the stereotyping process:

1. Most people know that it is not fair to discriminate against the unattractive (they would be incensed if others discriminated against *them*).
2. Privately, most people take it for granted that attractive and unattractive people are different. Generally, they assume that what is beautiful is good and what is unattractive is bad.
3. Most people treat good-looking and average people better than they treat the unattractive.
4. As a consequence, a self-fulfilling prophecy occurs. The way people are treated shapes the kinds of people they become. (Hatfield & Sprecher, 1986, p. 36)

There is evidence that people do perceive attractive and unattractive people differently. In one classic experiment, social psychologists showed college students yearbook photographs of men and women who varied markedly in appearance and asked them about their first impressions of the people depicted. Young adults assumed that handsome men and beautiful women must possess nearly all the virtues. The good-looking were assumed to be more sociable, outgoing, poised, interesting, exciting, sexually responsive, kind, nurturing, warm, modest, strong, and sensitive than

their homely peers. They were also expected to have happier and more fulfilling lives.

Not only do people think that the attractive are special, but they also treat them that way. Clinicians spend more time with good-looking clients. Teachers reward more attractive students with better grades. Executives are more likely to hire and promote good-looking men and women and to pay them higher salaries. The good-looking are more likely to receive assistance when they are in trouble. Attractive criminals are less likely to get caught, be reported to the authorities, be found guilty, or receive strict sentences than are others.

Society's biases give good-looking men and women a marked advantage in intimate relationships, as well. The attractive have an easier time meeting potential dates and mates, attract more appealing dates and mates, and end up with better dating and marital relationships. If, in spite of all these advantages, things go wrong, they find it easier to start anew.

What effect does such stereotyping have on men and women? It turns out that the good-looking and unattractive are not so different as people assume them to be. Self-esteem and self-concept are positively related to how good-looking people *think* they are, but not to actual appearance. In general, the personalities of the attractive and unattractive differ only slightly, if at all.

Attractive and unattractive people do seem to differ in one critical respect, however. The good-looking appear to be more confident in romantic and social situations and to possess more social skills than their peers. People expect the good-looking to be charming, so they treat them as if they are. As a consequence, the good-looking become more socially skilled.

This self-fulfilling aspect of physical attractiveness was demonstrated in a classic study by M. Snyder, E. Tanke, and E. Berscheid (1977). Men and women at the University of Minnesota were recruited for a study on the acquaintance process. First, men were given a Polaroid snapshot and biographical information about their partners. In fact, the snapshot was a fake; it depicted either a beautiful or a homely woman. Men were then asked their first impressions of this "potential date." Those who believed they had been assigned a beautiful partner expected her to be sociable, poised, humorous, and socially skilled. Those who thought they had been assigned an unattractive partner expected her to be unsociable, awkward, serious, and socially inept. Such prejudice is not surprising; it is known that good-looking people make exceptionally good first impressions.

The next set of findings, however, was startling. Men were asked to get acquainted with their partners via a telephone call. Men's expectations had a dramatic impact on the way they talked to their partners. Men who thought they were talking to a beautiful woman were more sociable, sexually warm, interesting, independent, sexually permissive, bold, outgoing, humorous, and socially skilled than were men who thought their partner was homely. The men assigned to an attractive woman were also more comfortable, enjoyed themselves more, liked their partners more, took the initiative more often, and used their voices more effectively. In brief, men who thought they were talking to a beautiful woman tried harder.

Within the space of a telephone conversation, women (regardless of their true appearance) became what men expected them to be. Women who were talked to as if they were beautiful soon began to sound that way. They became unusually animated, confident, and socially skilled. Those who were treated as if they were unattractive became withdrawn, lacked confidence, and seemed awkward.

The men's prophecies had been fulfilled.

A final observation: The evidence makes it clear that the good-looking have an advantage. However, a careful analysis of existing data makes it clear that the relationship between appearance and advantage is not a straightforward one. The extremely attractive have only a small advantage over their more ordinary peers. What is really important is to be at least average. Alas, it is the unattractive and the disfigured who suffer the greatest social costs of prejudice.

PHYSIOLOGICAL AND BEHAVIORAL CONCOMITANTS OF AGING

Many behavioral and psychological changes occur as one ages. To illustrate, we have described some of the age-related physiological changes in two sensory systems (vision

and hearing), the cardiovascular system, and the musculoskeletal system, and their behavioral and psychological effects. Many of these changes, however, are not inevitable consequences of aging.

Hearing

Various types of age-related hearing losses can occur (i.e., conductive, sensorineural, mixed, and central hearing loss; Heckheimer, 1989). These hearing losses may lead to specific hearing impairments. First, older adults may experience difficulty hearing high-frequency sounds (e.g., children's voices, squeaking brakes). Second, older adults may have trouble hearing information embedded in background noise (e.g., conversations in noisy environments). Consequently, older adults may frequently request that information be repeated, or they may rely on other contextual cues (e.g., lip-reading). Third, older adults may have more difficulty recognizing consonant sounds of shorter durations at lower decibel levels. Therefore, when conversing, older adults may ask speakers to talk louder. Similarly, older adults may increase the volume on radios or television sets. Fourth, older adults may experience more difficulty hearing rapidly presented speech with a low degree of context. Therefore, whenever novel information is spoken rapidly (e.g., messages over public announcement systems), older adult may miss important details. Fifth, older adults may experience difficulty hearing and understanding speech that lacks normal fluctuations in tone and rhythm (e.g., hearing unwavering speech or undifferentiated computer-generated speech).

These age-related declines in hearing may have additional behavioral consequences (e.g., social isolation or depression). Individuals may become irritated with their hearing difficulties and the speech characteristics of others that interfere with auditory perception. Further, older adults may even become paranoid about what others may be saying about them, perceiving others as "mumbling" or speaking softly to purposefully exclude the older listener.

Vision

Several age-related changes occur in the visual system that can have psychological and behavioral consequences. First, older adults require more light to see because of the increased density and opacity of their lenses, and the decreased number of photoreceptors (Whitbourne, 1998). Second, older adults are more likely to experience glare when viewing bright objects, due to the scattering of light within the lens resulting from the increased density. Third, older adults are more likely to experience difficulty with accommodation due to the increased lens density and the loss in flexibility of the eye capsule. Fourth, depth perception decreases with age, caused by the increased density of the lens. Fifth, age-related problems with color discrimination are caused by the increased yellowing of the lens and pigmentation of the vitreous humor. Finally, an age-related decrease in the visual field can be caused by macular degeneration, which is experienced by most individuals in their 70s and 80s.

The behavioral consequences of the foregoing problems can be quite significant. The increased difficulty in seeing objects in reduced light and greater susceptibility to glare can lead individuals to increasingly restrict their evening driving and walking. These changes in vision can also lead to increased accidents and falls resulting from failure to see hazardous objects, and diminished self-esteem resulting from such accidents and restrictions incurred from low vision. Changes in color perception can create difficulties in correctly matching clothing and facial makeup, and sometimes cause others to question the individual's aesthetic sensibilities (Whitbourne, 1998). These changes can also affect one's understanding of color-coded information and diminish one's appreciation of artwork, movies, and scenery. The diminished visual acuity can lead to difficulty reading, watching television, recognizing friends, and learning and remembering the distinctive features of the faces of new acquaintances. Finally, the embarrassment associated with these problems can lead to increased social isolation and decreased social activities.

Cardiovascular and Respiratory System

Age-related changes in the cardiovascular and respiratory systems can have significant behavioral and psychological consequences. However, not all older adults experience the same levels of decline of the cardiovascular and respiratory systems. Exercise, disease, and genetic predisposition are important factors, in addition to the effects of aging, in the determination of cardiorespiratory fitness.

Increased age is often associated with reduced cardiopulmonary fitness. The amount of blood ejected from the heart and the sensitivity of the heart to neural stimulation, which controls the timing and rate of heart contractions, decrease with age.

Aging also results in structural changes of the lungs (e.g., decreased elastic recoil and increased rigidity of chest wall) that limit lung capacity and the efficiency of the gas exchange. The consequences of cardiovascular and respiratory changes may include a decreased ability to cope with physical stress. The older adult may become more easily fatigued and experience shortness of breath more quickly compared to younger adults. Consequently, the older adult may become fearful of activities associated with physical exertion. Likewise, older adults may demonstrate frustration with the limitations associated with cardiovascular and respiratory changes and become more fearful of activities that cause physical exertion, and therefore pursue activities that are more sedentary. All of these limitations can also lead to lowered self-esteem.

Musculoskeletal System

Age-related musculoskeletal changes have important implications for the daily lives of older adults. Muscle mass decreases with age and can lead to increased weakness. Muscle endurance also diminishes with age. Bone mass and porosity decreases, increasing susceptibility to fractures. The joint cartilage also degenerates with age, resulting in increased joint pain and stiffening. Musculoskeletal changes can be reduced (e.g., increased muscle strength and endurance) in both younger and older adults via exercises.

Age-related musculoskeletal changes may result in older adults restricting movements and being less willing to undertake physically demanding tasks. Older adults may become more easily fatigued and more cautious in their movements, particularly on slippery surfaces. Individuals may demonstrate difficulty climbing stairs or rising from a sitting position. Fear of falling may develop because of leg weakness or fear of breaking bones when ambulating. These musculoskeletal changes may restrict participation in enjoyable/leisure activities and diminish self-esteem. The chronic pain sometimes associated with musculoskeletal changes can also lead to depression.

In summary, numerous changes occur in the aging body that can have substantial behavioral and psychological effects. Fortunately, the human body exhibits amazing resilience, accommodation, and adaptation to the aging process.

PHYSIOLOGICAL PSYCHOLOGY (NONREDUCTIONISM)

Any serious consideration of a nonreductionist approach to physiological psychology calls for a prefatory definition in an effort to achieve a thorough comprehension of the pivotal term *reductionism.* The order ranges from physics, the simplest, to sociology, the most complex (Figure 1). The reductionist believes that all the diverse forms of nature are continuous and result from different combinations of the same basic elements. Reductionists conclude that the ultimate nature of the universe is reducible to those fixed and

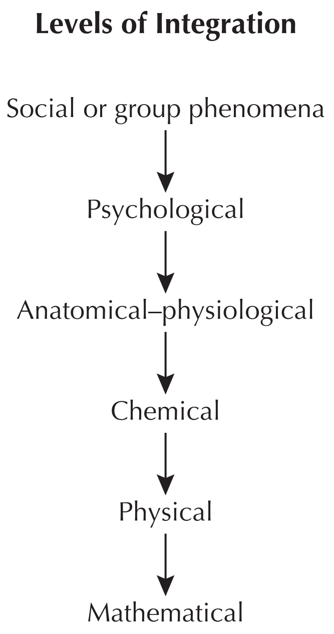

Figure 1. Hierarchy of the sciences arranged according to levels of complexity.

indivisible atomic building blocks. According to reductionists, that is the way to understand all aspects of nature.

At one time, the reductionist could have safely clung to the belief that at some time in the future, sociological, psychological, biological, and physical events would all be explained in terms of the fixed and eternal building blocks of physics. However, the absolutistic reductionist now is confronted by the embarrassing discovery of contemporary physics that atomic particles themselves have very elusive properties, hardly a dependable base on which to erect a firm theoretical structure.

Reductionism in Biology

For its particular area of investigation, biology segregates living things, both plants and animals. Subdivisions of biology deal with cells (cytology), tissues (histology), anatomy or morphology, physiology, and embryology. Cells, tissues, organs, and organisms have properties beyond those found in molecules. Among them are organization, coordination, control, adaptation, growth or duplication, and repair. Although there are no phenomena in living systems that are not molecular, there also are none that are only molecular.

The cell shows a certain characteristic unity, pattern, order, and integration not found in the molecular constituents of cells. The organism also shows properties that cannot be inferred from its constituent organs. The word *organism* refers to organization, the hallmark of the living thing, plant or animal. It acts as a unit—as a system, not as a collection of independently acting, helter-skelter organs, tissues, cells, or molecules.

Opposed to the notion of reductionism is the concept of

wholeness and levels of integration. According to holism, each cell, tissue, organ, or organism is more than the sum of its parts. A converse statement would say, in effect, that in describing a cell in terms only of its component molecules, some aspects of that cell would be left out. Knowledge of the individual parts would not yield understanding of the whole, except by seeing the role of the parts as an expression of the whole organism.

The concept of integrative levels may help to clarify a nonreductionistic approach to natural events. According to this notion, the order of sciences in Figure 1, from physics up to sociology, reflects levels of integration. Thus, in place of reductionistic continuity, there is discontinuity at each level, beginning at physics. At each higher level, new qualities emerge that were not apparent at lower levels. The implication is that events at each level must be studied at their own level instead of being forced into a lower mold. To reduce phenomena at a higher level to a lower level would be to lose the attributes and structure of the observations that initiated inquiry.

The Role of the Hypothetical Construct

In some sciences, such as physics and biology, some phenomena can be analyzed to the point at which sight and touch give out and the investigator is forced to resort to submicroscopical concepts—an undesirable situation and certainly not one to be emulated. The relationship between what is perceived and what is conceived in explanatory terms sometimes becomes highly attenuated.

How can the troubles that reductionism presents be avoided? A different procedure is tried. This time, a field approach of the interbehavioral type is adopted in investigating psychological occurrences. A first requisite here will be to broaden views to include organism and stimulus object. With this change in orientation, the focus shifts away from the reductionist's concentration on the organism. The center of interest now concerns not what might be imagined to be going on inside the organism, but what transpires between the organism and stimulus object. Their interaction is of paramount, but not exclusive, preoccupation because there are additional observable variables. The interaction requires light to mediate visual interactions and air for auditory interactions. No event occurs in a vacuum, so the setting factors or surrounding conditions in which the event occurs must be noted. All of these aspects of the total event must be seen in system, in their totality. It is hardly possible to overstress the equal emphasis given to the stimulus object, a view that certainly deglamorizes the organism.

Scientists come to accept certain events that fit a dependable regularity or "ideal of natural order" as self-explanatory. There is no need to go behind the scenes or to ask further questions. These occurrences are accepted as the starting point or base for explaining other things. Gravitation offers a convenient example. Note the gravitational interaction between the Earth and the Moon. It would not profit the astronomer to ask, "Why is there gravity?" The fact is that there is gravity, and the problem is to determine how, what, when, and where it operates. A rejection of the rock-bottom concept would be illustrated by an investigator who insisted on tearing apart the Earth and the Moon in an attempt to find the "cause" of gravity. Modern astronomers know better than to join such a foolish enterprise. They accept gravity as a fact that requires no further explanation, and go to work convinced that gravitation just *is*.

The concept of "rock-bottom" can be applied to psychological inquiry. For nonreductionistic physiological psychologists, the organism is rock-bottom. They do not need to dissect it for some imaginary internal "cause" of behavior any more than the astronomer feels compelled to search within the bowels of the Earth or the Moon for the "cause" of gravity. Nonreductionists accept the organism as one of the variables and as a starting point for inquiry, an inquiry that relates the unitary, integrated organism to the stimulus and to other components of the total field. In summary, the difference between reductionistic physiological psychologists and the nonreductionistic variety is what they accept as rock-bottom. For the former, rock-bottom lies somewhere inside the organism's head; for the nonreductionist, the organism itself is rock-bottom.

The Organism as a Locus of Variables

It would appear as if the nonreductionist's acceptance of the organism as rock-bottom implies a complete neglect of the biological aspects of the living copartner of a psychological event. This is not so. On the contrary, the nonreductionist looks on the organism as an important locus of variables than can affect the psychological event. An example using two scenarios in which a boy is reading a book can help make the point in a broad way. In both Event A and Event B, the boy and the book are interacting under definite and specific conditions. Among these are a certain illumination, quiet, 70°F temperature, and so on. However, prior to Event B the boy suffered damage to his brain. The important point is that Event A does not equal Event B. The brain concussion as a significant variable has changed the boy. Thus the boy in Event B is not the same boy as the one who participated in Event A. Therefore, the two events are not comparable. Reading that proceeded smoothly in Event A has been interfered with in Event B by a variable localizable within the biological matrix of the boy.

For the nonreductionist, such an explanation is rock-bottom and it is satisfying, but it only spurs the reductionist to search within the brain somewhere for a "why" kind of explanation for the boy's changed reading behavior. This procedure can only lead us back to "merely conceivable" explanations, which themselves call for verification before they can be used.

The difference between the reductionist and nonreductionist view of the nervous system can be summed up by

characterizing the nervous system as a necessary but not a sufficient condition for proper verbal behavior.

Our consideration of the nervous system as a necessary but not sufficient condition of psychological occurrences paves the way for an expanded inquiry into the question of the organism as a locus of variables. Specifically, this calls for an inventory of the anatomical-physiological aspects of the organism that are involved in various psychological events. For example, in speaking, such parts as the oral cavity with lips, teeth, and vocal chords, and the trachea, lungs, and diaphragm participate in interactions. Yet even here there are no absolutes, as people without vocal chords or tongue have been able to produce speech. However, no amount of minute anatomical-physiological description can explain how it is that one person speaks French, another speaks Swedish, and still another speaks Russian. Also, it is granted that a Beethoven born deaf would never have become the superb composer that he was. Yet the fact that he became deaf did not prevent him from composing the bulk of his work after his tragedy. There is a suggestion here of the domination of the flesh by the psychological. Certainly legs and arms are of crucial importance in football or baseball activities; however, some leg amputees can swim. Nevertheless, any departure from an optimal intactness of the organism can act in a negative way. Blindness can prevent visual interactions, but so can absence of illumination. If we think of the former condition as more permanent, how about a sighted person's life imprisonment in a pitch-black dungeon? The two conditions are then equated, and, because either can have devastating consequences, neither condition is exalted above the other, as either can extinguish visual interactions. With the view of the organism as rock-bottom, the nonreductionist holds that a maximal intactness of the organism is desirable.

Conclusions

Because reductionism deals with imputed properties of the nervous system, we must take note of the circular reasoning underlying the hypothetical construct and reject theories that are "merely conceivable." As an alternative, the organism might be regarded as a locus of variables that can either facilitate or interfere with psychological events. As such, they are considered part of the total psychological event. A nonreductionist view avoids problems such as treating the nervous system (1) as causal (i.e., as producing psychological action), and (2) as having dual functions, biological and psychological—problems created by a reductionistic approach.

PIAGET'S THEORY

Over the course of 60 years, Jean Piaget (1896–1980), a Swiss biologist and philosopher, formulated a theory of the development of intellectual competence that continues to influence contemporary theories in that field. Piaget maintained that logical thought depended on learning, social cooperation, biological maturation, and *development,* by which he meant a series of fundamental changes such that the later ways of thinking are dependent upon, yet qualitatively distinct from, the earlier ones, always moving in the direction of greater logical consistency. He formulated subsidiary theories of the development of moral judgment and reasoning, perception, images, and memory, always from the perspective of how each was constrained by the various levels of intellectual competence.

Genetic Epistemology

Genetic epistemology is a discipline founded by the American psychologist James Mark Baldwin that draws upon philosophy, psychology, logic, biology, cybernetics, and structuralism and addresses all aspects of such questions as: What is knowing? From whence does it come? What conditions make it possible? Genetic epistemology, as formulated by Piaget, attributed the development of knowledge and intelligence within the individual and within Western scientific cultures to coordinated mechanisms that simultaneously sought to preserve and to modify the underlying structure of the mind and the culture.

Piaget held that the fundamental structures of our minds are not given a priori, but are humanly constructed through evolving systems by which we act on and transform the environment and our own minds. The succeeding levels or stages are always reformulations or reconstructions of our preceding ways of acting on the world and validating knowledge. Subsequent stages are always a more consistent way of acting on the world, and are always more coherent, than the stages that precede them.

The Epistemic Subject

Piaget's theory of intellectual development is about an idealized person, a person who probably does not exist, but who could exist. The person is the *epistemic subject,* the pure knower who has no individual characteristics—no personality, sex, motivation (other than to know), culture, nationality—and the theory is about that person. Although Piaget's theoretical description of a child's competence at logical problem solving does not fully account for what a given child will do in a problem situation, it does characterize what a child can do if no other mitigating factors are present. While the epistemic subject merely understands and knows events, the ordinary person succeeds in any number of tasks, and often without any understanding of

this success. In fact, this lag between success on a task and understanding the task is a topic that Piaget addressed in his later work.

The epistemic subject knows those truths that are necessarily true as opposed to those that are merely true. For example, when A = B and B = C, not only is it true empirically that A = C, but it is necessarily true; it must be true, it could not possibly be otherwise, and there is no need to examine A and C in any way to know that A equals C. At its core, Piaget's theory is about the development of truths that have to be as they are and could not conceivably be otherwise.

The Clinical Method

In Piaget's clinical research, each child was seen individually, given some materials or an apparatus to manipulate, and asked questions designed to elicit responses about what he or she did. What the child said or believed about what was done was important, but greater emphasis was placed upon what the child actually did, how the problem was tackled, what errors the child made, and so forth. Invariably, the child was asked to think about a common childhood event, such as flattening a clay ball or playing marbles, in a new way, or to consider a new possibility in an ordinary childlike task, such as lining up sticks in order by their lengths.

The tasks or problems set for the children were usually designed to reveal the structure of the child's reasoning about some epistemological question, such as the nature of causality, necessity, implication, time, or space.

The Stages of Intellectual Development

Piaget claimed only that he had developed a general outline or skeleton of a theory, with gaps to be filled in by others. Even the number of stages of intellectual development varied in his work from time to time, but most accounts set forth four main stages: the *sensorimotor stage* (0–2 years), with six substages; the *preoperational stage* (2–7 years), with two substages; the *concrete operational stage* (7–12 years), with two substages; and the *formal operational stage* (12 years and up). Within each stage and substage, Piaget frequently distinguished three levels: failure, partial success, and success. In the final versions of the theory, development was viewed not as linear progression through the stages, but as an open-ended spiral in which the differentiated forms and content at one level are reworked, restructured, integrated, or synthesized at the higher levels of the spiral.

Sensorimotor Stage

The six substages of this stage show the following developments: The infant exhibits (1) innate reflexes and an inability to think, have purpose, or distinguish him/herself from the surroundings; (2) reflexes extended to repetitive actions; (3) the ability to reproduce fortuitous, pleasant, and interesting events; (4) increased coordination of ways to make the interesting things last; (5) discovery of new ways to produce interesting results; and (6) an ability to represent absent events symbolically. The principal accomplishments are the construction of coordinated movements, which have a grouplike mathematical structure; the construction of representation; and the idea of permanent objects and intentionality.

Preoperational Stage

This stage has often been characterized primarily by what the child cannot do. Thought seems rigidly captured by one aspect of a situation, often the child's own point of view (egocentrism), to the exclusion of other perspectives. Thought, besides being centered on a single salient feature of an event, seems to flow in sequences of simple juxtaposition rather than sequences of logical implication or physical causality. Children's reasons for their responses are often preposterous fabrications, or justifications at any price.

Concrete Operational Stage

The errors the child makes during the preoperational stage are corrected in the subsequent stage, but not uniformly or all at once. The solution to problems is worked out separately in various domains. For example, the notion of invariance (conservation) is acquired separately and sequentially in the following order: number, length and mass, area, weight, time, and volume.

Formal Operational Stage

The young adolescent is able to consider all possibilities and to vary all but one in an analysis of a physical event. The ability to hypothetically vary all but one of the possible dimensions of a situation means that form can be considered and manipulated apart from its content and that reality can be subservient to possibility.

Neo-Piagetian Theory

Subsequent work by "neo-Piagetian" theorists has reinforced and expanded Piaget's constructivist stance. Piaget's followers have argued for ongoing intellectual development beyond adolescence that extends *formal thought* to new areas, but based on structures that are less universal, more domain specific, and associated with areas of schooled expertise. The course of development in this view was taken to be more gradual, less punctuated, more socially and culturally dependent, and more integrated with other mental

functions (like emotion and motivation) than in many interpretations of Piaget's initial formulations.

PICK'S DISEASE

Pick's disease was first described by Arnold Pick in 1892 to describe non-Alzheimer's neuropathological changes in an individual with left anterior temporal atrophy and spared frontal lobes. It is a relatively rare and possibly heritable progressive neurodegenerative disorder appearing 10 to 20% as often as Alzheimer's disease. Duration of the disease from diagnosis to death is 5 to 10 years (Tissot, Constantinidis, & Richard, 1985). The disease typically affects individuals between the ages of 45 and 65 years (Hodges, 1994). In Pick's disease patients, brain imaging and autopsy examinations characteristically display progressive frontotemporal lobar atrophy. Due to clinical overlap with other cortical dementias, neuropathologic confirmation is required to establish a definitive diagnosis of Pick's disease.

Neuropathology of Pick's Disease

Pick's disease results in atrophy of the anterior portion of the frontal lobe and a characteristic atrophy of the anterior portion of the superior temporal gyrus (anterior to the central sulcus) with preservation of the posterior portions of that gyrus. The parietal and occipital lobes are generally spared. The atrophy leaves the gyri with a knife-edge appearance. The lateral ventricles, particularly the frontal horns, are dilated due to the atrophic changes. There is also a characteristic severe loss of the granular neurons that comprise the dentate gyrus of the hippocampal complex. Subcortical structures in which neuronal loss occurs include the basal ganglia, amygdala, nucleus basalis of Meynert, substantia nigra, and locus ceruleus (Hof, Bouras, Perl, & Morrison, 1994; Hansen, 1994). Brain stem and cerebellar areas with connections to the cortex are also typically involved (Braak, Arai, & Braak, 1999; Dickson, 1998). In contrast to severely abnormal computed tomography or magnetic resonance images, electroencephalographic recordings are usually normal.

Neuropathologic features of Pick's disease include severe cerebral cortical neuronal loss, Pick bodies, and ballooned neurons (Pick cells; Giannakopoulos et al., 1996). Pick bodies are intracytoplasmic argyrophilic neuronal inclusions composed of straight filaments, microtubules, and occasional paired helical filaments (similar to those in Alzheimer's disease neurofibrillary tangles; Hof et al., 1994). Although there is some neuronal loss in the nucleus basalis of Meynert, cortical levels of choline acetyltransferase are not reduced in Pick's disease as they are in Alzheimer's disease.

Cognitive Changes in Pick's Disease

Clinical manifestations of Pick's disease reflect the distribution of neuropathological changes. Cognitive deficits typically follow alterations in personality and behavior. Behavior changes may include disinhibition, impulsivity, apathy, and decreased initiative. Patients may begin to exhibit inappropriate social behaviors and neglect personal responsibilities. Emotional changes vary and can include depression, anger, mania, irritability, or lability. Patients commonly lack insight into their behavioral and personality changes. Due to severe atrophy of the frontal lobes, patients with Pick's disease have marked impairments in planning and organizing complex activities, set-shifting, judgment, sequencing, and sustaining attention. Their inability to sustain attention and organize activities can give a misleading impression of memory impairment. However, patients generally have preserved memory function evident by cue-enhanced immediate memory and information retrieval abilities. Patients with Pick's disease may have language disturbances characterized by echolalia and perseveration, reduced production of speech, use of stereotyped phrases, and late mutism. Articulation, syntax, and phonology are generally preserved. General intelligence, orientation, perceptual skills, and visuospatial abilities are often intact. In addition, sensory, motor, and reflex functions remain normal through most of the disease (Mendez, Selwood, Mastri, & Frey, 1993; Hodges, 1994; Mendez et al., 1996).

Comparison of Pick's and Other Neurodegenerative Diseases

As cognitive and behavioral performance progressively deteriorate, it becomes increasingly difficult to differentiate Pick's disease from other cortical dementias such as Alzheimer's disease and necessitates neuropathologic confirmation (Arnold, Hyman, & Van Hoesen, 1994). Pick's disease causes extensive atrophy and gliosis throughout the frontal lobe and anterior temporal lobe, most prominent in cortical layer three. Pick bodies are most evident in the insula and inferior temporal cortex. Loss of hippocampal dentate gyrus granular neurons with relatively preserved pyramidal neurons is characteristic of Pick's disease, while in Alzheimer's disease there is early loss of hippocampal pyramidal neurons with preservation of the dentate gyrus neurons. Nearly three fourths of Pick's disease patients display early personality changes and behaviors such as roaming, hyperorality, and disinhibition, while less than one third of Alzheimer's disease patients have such symptoms. These behaviors correlate with the greater frontal and temporal lobe damage in Pick's disease.

In addition to the clinical overlap of Pick's disease with Alzheimer's disease, the neuropathologic features of Pick's disease overlap with those of frontal lobe dementia, primary progressive aphasia, corticobasal degeneration, and multisystem atrophy. Therefore, attempts have been made to differentiate Pick's disease from progressive supranuclear palsy and corticobasal degeneration (Feany, Mattiace, & Dickson, 1996). All three disorders have abnormalities of cortical and subcortical regions; however, Pick's disease has more cortical involvement, progressive supranuclear palsy has more subcortical damage, and corticobasal degeneration has equal cortical and subcortical pathology. The three disorders all have significant pathology in the substantia nigra, subthalamic nucleus, and locus ceruleus. However, Pick's disease has greater numbers of ballooned neurons than the other diseases; corticobasal degeneration can be distinguished by numerous neuropil threads in gray and white matter and neurofibrillary tangles in the globus pallidus; and progressive supranuclear palsy has numerous tangles in the globus pallidus with few neuropil threads or ballooned neurons. Thus, although there are significant overlaps, neuropathologic changes are relatively distinct for each disorder, suggesting separate pathophysiologic entities. Because of the neuropathologic similarities, these latter disorders have been grouped together under the heading "Pick's complex."

More recently, however, Pick's disease has become subsumed under the rubric of frontotemporal dementia in order to reflect the distribution of the pathologic changes rather than the exact histological subtypes of dementias. Three clinical subtypes of frontotemporal dementia are now recognized by the scientific and medical community: frontotemporal dementia, of which a portion of cases are pathologically confirmed as Pick's disease; semantic dementia; and progressive nonfluent or primary progressive aphasia (Neary et al., 1998).

PITUITARY

The name *pituitary* was applied to the small gland beneath the brain's hypothalamus in the early seventeenth century because of the mistaken notion that the structure made phlegm; hence the name *pituitary,* which literally means "snot gland." Hypophysis is a less colorful name for the pituitary.

For descriptive, embryological, and functional reasons, the pituitary is divided into two lobes: the anterior lobe or adenohypophysis and the posterior lobe or neurohypophysis. The structure is connected to the hypothalamus by the infundibulum or hypophyseal stalk. A schematic drawing of the pituitary is shown in Figure 1.

Anterior Lobe or Adenohypophysis

Because of its role in the control of other endocrine glands, the pituitary is often called the "master gland of the body." This designation is more appropriately applied to the pituitary's anterior lobe than it is to the posterior lobe, as the adenohypophysis manufactures and secretes hormones that regulate the body's most important glands (e.g., the adrenal glands, the thyroid gland, the gonads). In fact, the prefix "adeno-" means *gland.*

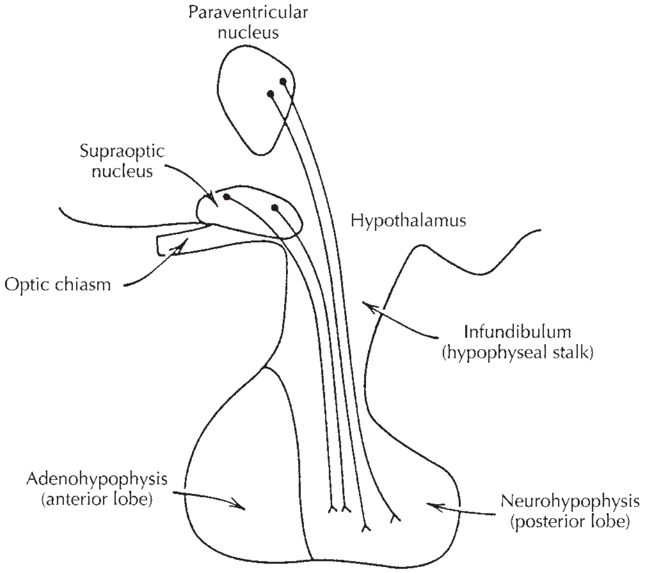

Figure 1. Schematic drawing showing the relationship of the posterior lobe (neurohypophysis) to the hypothalamus. The anterior lobe (adenohypophysis) is functionally connected to the hypothalamus by blood vessels (not shown).

The anterior lobe of the pituitary is derived from skin cells from the roof of the mouth, and the surgical approach to the pituitary is through the roof of the mouth, which will give you a better appreciation of the gland's location in your head. Although it is not in direct neural contact with the brain, the activities of the adenohypophysis are regulated by the hypothalamus, which secretes neurochemicals termed "releasing factors" that travel to the anterior lobe through a system of blood vessels called the hypothalamo-hypophysical portal system.

The releasing factors are peptides and they modulate the secretion of anterior lobe hormones such as somatotropin, thyrotropin, adrenocorticotropin, lactogenic hormone, and the gonadotropins. Each will be discussed briefly.

Somatotropin (STH) is a growth-promoting hormone and, in fact, is usually called *growth hormone.* Its presence at appropriate developmental periods is essential for normal growth. Too much can produce a distorted growth problem called acromegaly; too little results in dwarfism.

Thyrotropin (TSH or thyroid-stimulating hormone) acts on the thyroid gland to promote the synthesis, storage, and release of the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3). Thyroid hormones are involved in the regulation of the body's metabolism.

Adrenocorticotropin (ACTH or adrenocorticotropic hormone) stimulates the production and release of hormones by the adrenal cortex (the adrenal glands are above the kidneys). ACTH triggers the release of glucocorticoids (e.g., cortisol), which are important in carbohydrate metabolism and in the body's resistance to stress. ACTH itself is released in response to physical or emotional stress.

Lactogenic hormone (LTH or prolactin) acts on the mammary glands to promote milk secretion. Prolactin may also be important for the display of parental behaviors in vertebrates.

The *gonadotropins* (luteinizing hormone and follicle stimulating hormone) act on the gonads. Luteinizing hormone (LH) is necessary for ovulation in females. In males, LH acts on cells in the testes to cause them to produce testosterone.

Posterior Lobe or Neurohypophysis

Unlike the anterior lobe, which receives no direct neural innervation, the posterior lobe of the pituitary or neurohypophysis contains the axonic nerve terminals of two hypothalamic nuclei: the supraoptic and the paraventricular. The supraoptic nuclei predominantly synthesize vasopressin, known as antidiuretic hormone (ADH). ADH acts primarily on the kidneys to regulate water balance. Lack of ADH secondary to disease, trauma, or genetic vulnerability causes diabetes insipidus, a serious disorder characterized by excessive drinking and urination.

The paraventricular nuclei predominantly manufacture oxytocin, which is a smooth muscle-contracting hormone. Oxytocin plays an important role in inducing the contractions of the uterine walls during the birth process; that is, oxytocin is responsible for labor pains. In addition, it is required for the release of milk in response to suckling. In males, oxytocin regulates prostate gland function.

PLACEBO

Placebo is derived from the Latin meaning "to placate or please." Shapiro (1960) defines placebo as "any therapy (or that component of any therapy) that is deliberately used for its nonspecific psychologic or physiologic effect, or that is used for its presumed effect on a patient's [symptom or illness] but which, unknown to patient and therapist, is without specific activity for the condition being treated" (p. 109).

The Ubiquitous Placebo

Patients have always been soothed by medicines that do not work psychopharmacologically. The files of the FDA are full of once-new miracle drugs that have mysteriously become ineffective over time.

The placebo response has been positive in studies of adrenal gland secretion, angina pain, blood cell counts, blood pressure, cold vaccine, common cold, cough reflex, fever, gastric secretion/motility, headache, insomnia, measles vaccine, oral contraceptives, pain, pupil dilation/constriction,

rheumatoid arthritis, vasomotor function, vitamins, warts, and other ailments. Placebo medication has inhibited gastric acid secretion; soothed bleeding ulcers; and mimicked the effects of amphetamine, ipacac, and LSD, as well as most psychoactive drugs. It has reduced adrenocorticol activity and serum lipoproteins. It has been used in drug withdrawal studies as a substitute for morphine, Talwin injections, and Naloxone. Placebo side effects mimic medication side effects, and placebo effects have been documented in studies of psychotherapy, acupuncture, hypnosis, and behavioral treatments for insomnia and pain. Such surgical and dental procedures as Ligation of mammary arteries for angina pain, and bruxism have been shown to be as ineffective as placebo.

There is a dearth of placebo controlled studies on the plethora of over-the-counter medications, nutritional supplements, and new treatments: Many turn out to be no different from powerful placebos. The mutual expectations and faith in the treatment's efficacy provide the therapeutic ingredient. Theories about the mechanisms underlying placebo effects include discussions of the role of anxiety, conditioning, endorphins, experimenter bias, and suggestion. The role of belief and expectation in mediating the placebo response seems to have the most empirical support.

The placebo response has been viewed as a nuisance variable in methodological studies. It can have powerful negative therapeutic effects, called *nocebo effects.* Patients may show symptoms when they first learn what side effects may be expected, and iatrogenic effects may follow completion of informed consent for medical procedures.

The Placebo Effect in Double-Blind Trials

Placebo response is a control procedure in pharmacological studies. Medication may be given in a double-blind condition so that neither the patient nor the researcher/clinician knows whether a medication or a placebo has been administered. The placebo effect is considered a nuisance variable. Because of the reactive nature of all research, the effects of the interpersonal doctor-patient relationship, and the drug-giving ritual, the expectation is communicated that relief of symptoms is imminent. Under double-blind conditions, the maximized placebo response is subtracted from the active medication effect, leaving the net medication effect.

There are methodological difficulties with the classic double-blind procedure. The researcher rarely collects data from both patient and observer concerning which agent they believe was administered. The investigator's guess about whether a patient has received the drug or the placebo is more correlated with the results than whether the patient received the drug or the placebo. In treatment studies in which the placebo effect is atypically low compared to an active treatment, it is likely that the blind code was inadvertently broken by the many cues influencing a patient's response.

Clinical Significance of Placebo

Beecher (1959) reviewed 15 double-blind studies of morphine treatment of postoperative pain. He reported that 35% of these patients experienced pain reduction comparable to patients given a standard injection of morphine. Beecher's 35% clinical efficacy fails to recognize that even a standard dose of morphine was effective in only about 70% of patients. Evans (1974) used an index of placebo efficiency, comparing the effectiveness of placebo with the effectiveness of morphine, and found placebo was 56% as effective as morphine. Similarly, averaging available double-blind studies since Beecher's review, placebo is about 55% as effective as Aspirin, Darvon compound, Codeine, and Zomax. These consistencies imply that the placebo response is proportional to the assumed efficacy of the treatment itself. Similar ratios are found comparing double-blind studies of antidepressant and sleep medications to placebo.

The placebo effect has powerful positive therapeutic implications. The placebo response is apparently mediated in all treatment contexts by expectancy, anxiety reduction, and cues that emanate from the subtleties of the doctor-patient relationship. Studies have shown that the placebo response is not related to suggestibility, gullibility, conformity, hypnosis, or related traits.

Clinical Applications of Placebo

Under what circumstances should placebos be actively prescribed? Physicians admit they have occasionally used placebos knowingly, but less than their colleagues in other specialties. This unfortunate negative view of the placebo denies the significance of the doctor-patient relationship. Some critics argue that placebos are inherently unethical because deception is involved. From the point of view of the patient, the contract with the physician is to get better; therefore, one might question whether it is unethical to deny treatment that may be effective, inexpensive, and relatively safe.

The placebo has several clinical applications:

1. It involves mechanisms that will lead to improved treatment.
2. Placebo may be a powerful diagnostic tool. For example, anesthesiologists may use placebo nerve blocks for diagnostic purposes. Unfortunately, wrong conclusions may be drawn: Some physicians have incorrectly equated response to a placebo diagnostic test with the belief that the symptom (e.g., pain) is "psychological."
3. A positive placebo response indicates that the patient has the resources to manipulate and control symptoms at some level. A positive placebo response will often predict a positive therapeutic outcome.
4. The nonspecific placebo effects and the specific treatment effects are interactive and cumulative. Place-

bos can sometimes be used as an alternative to medications as a substitute for potentially dangerous drugs, and as an aid in withdrawal from active or addictive medication.

Summary

The placebo effect is a significant part of the total treatment context. The nature of the doctor-patient relationship and the expectations of treatment and cure that are communicated in this context provide the basis for powerful nonspecific therapeutic interventions.

PLANNED SHORT-TERM PSYCHOTHERAPY

Although occasional references to short-term psychotherapy appeared prior to the inauguration of the community mental health movement in the early 1960s, serious examination of brief psychotherapies began at the same time that mental health professionals recognized the importance of serving the mental health needs of the entire community. Time-limited psychotherapy was thought to be a strategy that had the potential for helping greater numbers of clients in the community.

The literature on planned short-term psychotherapy has increased exponentially since then until there are now nearly 200 books and 4,500 published papers on the topic. No school of psychotherapy has been unaffected by this literature. There are now numerous descriptions and outcome studies of planned short-term individual and group approaches to psychodynamically oriented, cognitively and behaviorally oriented, solution-focused, and strategic psychotherapies with both children and adults in both inpatient and outpatient settings.

This growing literature has had a profound impact on the funding and practice of psychotherapy primarily because of its consistent evidence that planned short-term psychotherapies, often as short as a single interview, generally appear to be as effective as time-unlimited psychotherapies, virtually regardless of client characteristics, treatment duration, or therapist orientation. Furthermore, almost identical findings have been reported for short-term inpatient psychiatric care.

Health economists concerned about the alarming increase in the cost of medical care could hardly have been expected to ignore the evidence that, in the case of psychotherapy at least, longer is rarely better. Indeed, were it not for the consistent evidence of the effectiveness of planned short-term psychotherapy, the writings in this field might have ended up simply as a footnote in the ongoing history of psychotherapy. What seems to be happening in the practice of psychotherapy parallels what is happening in general health services. Treatment has become shorter rather than longer, is taking place increasingly in outpatient rather than inpatient settings, and is less, rather than more, invasive.

Planned short-term psychotherapy is not simply less of time-unlimited psychotherapy. Rather, the practice of planned short-term psychotherapy rests on four fundamental principles uniquely associated with it that distinguish it from traditional time-unlimited approaches. Furthermore, evidence suggests that training in these principles and their application improves the clinical effectiveness of therapists.

First, research studies have consistently found that improvement during an episode of psychotherapy is negatively accelerated—very rapid at first, then slowing significantly. Accordingly, therapists who are interested in making the best use of time take advantage of the initial period of rapid improvement by keeping episodes of therapy as short as possible while at the same time encouraging clients to return for additional brief therapeutic episodes when they are needed. Whereas traditionally trained psychotherapists tend to think that when a client returns to treatment it is a sign that the initial treatment episode was a failure (an assertion for which there is little if any empirical evidence), planned short-term psychotherapy is designed to be intermittent—multiple individual brief treatment episodes within an ongoing therapeutic relationship.

Second, brief psychotherapy is especially empowering to the therapist. The evolution from time-unlimited to planned short-term psychotherapy results in a fundamental change in the role of the therapist—from a passive one in which the gradual deconstruction of conflict is observed to a more active one in which the therapist takes a directive stance in helping plan every aspect of the clinical episode. Planned short-term psychotherapy requires an active collaboration between client and therapist in establishing therapeutic goals, conducting the therapeutic episode, and bringing it to an agreed-upon conclusion.

Third, in contrast to traditional time-unlimited psychotherapies that place unique therapeutic importance on the face-to-face clinical contact, planned short-term psychotherapies assume that the time between clinical contacts and after the conclusion of a clinical episode has significant therapeutic potential. Accordingly, the therapeutic episode is designed to use the time between sessions planfully and to start a therapeutic process that can continue after the face-to-face contacts have been brought to an end.

Small changes during the treatment episode may be all that is required to start a process that will lead to significant and long-lasting clinical improvement. An episode of psychotherapy is thought of as a starting place rather than a completion of the change process. In addition, numerous empirical studies have also identified the so-called *sleeper effect,* evidence that the effects of psychotherapy continue, and often increase, long after the therapeutic episode has been concluded. One way that planned short-term psychotherapists build on this sleeper effect is to include a planned follow-up contact into the therapeutic episode. Such posttreatment contacts not only create a unique opportunity to evaluate the consequences of their work, but also appear to extend the life and the effectiveness of therapeutic interventions.

Fourth, time-conscious therapists think of each client contact as a self-contained unit, an opportunity to accomplish a significant, focused piece of clinical work so that additional contacts may not be necessary. A therapeutic episode is thus thought of as a series of single sessions. In contrast to traditional psychotherapists, who tend to underestimate how helpful they can be to people in brief periods of time, therapists who practice planned short-term psychotherapy believe that virtually all clients can be helped and can be helped relatively quickly, regardless of diagnosis or problem severity. The psychological climax of every interview is intended to be a skillful intervention—a well-timed interpretation, a carefully considered activity plan designed to modify undesired behavior, or a proposal whose goal is to change interpersonal interaction.

There are numerous cases, of course, in which psychotherapy needs to be extended in order to achieve satisfactory results. These instances can rarely be predicted in advance, however, and mental health professionals are learning to make time available to treat clients who need longer-term psychotherapy by making sure that all their clients receive only the psychotherapy they need, but no more.

For nearly 40 years the empirical literature has underlined the remarkable efficacy of planned short-term psychotherapy. The theoretical literature is equally impressive in helping put these new clinical practices in a conceptually rich and historically revered context. Mental health professionals, while properly insisting on avoiding undertreatment, are beginning to accept the affirmation of their effectiveness in brief periods of time and are increasingly alert to avoiding overtreatment as well.

PLAY

Play is variously regarded as a “cobweb,” an “omnibus term,” or even a category not useful for psychology. This is probably so because play manifests itself in so many forms that it is difficult to find a commonality of structure or function in all these activities.

There are two main approaches to an understanding of play, and these are distinguishable in its motivation and goal. In the more commonly held view, play is an exotelic activity and a rehearsal for the acquisition of greater competence. Play is an activity performed generally by children and young people, and exists so that they can rehearse actions that will increase competence and promote maturity. Thus, play is an outcome variable with the reward to be found extrinsic to the activity. Advocates of this view argue that competence is enhanced by appropriate and adequate play opportunities. Some even argue that the very existence of youth is largely for the sake of play.

In the autotelic view, regardless of its form or structure, play is seen to be motivated by an interaction of the conditions of the player with those of the environment (both external and internal). The environment must contain elements conductive to an interchange with elements in the motivational state of the individual. This produces activity characterized by pleasure, interest, and reduction of tension. The elements that produce playful behavior are similar to those that evoke curiosity and produce exploratory behavior.

Piaget, following an exotelic approach, based his taxonomy of play on his theory of cognitive development, arguing that at each stage of development certain types of play become predominant. Thus, in the sensorimotor stage (the first 2 years of life), practice play is common. This consists of repetition of patterns of movement or sound, beginning with sucking and babbling, finally developing into reacting with the environment in ways in which activities are varied systematically and their effects are monitored.

After the second year, the child moves into the preconceptual stage with the ability to master symbolic functions. Games reflect this change by becoming symbolic—games of make-believe. These games are exemplified by the child’s use of objects as things different from their apparent intention. Children also begin to place themselves in symbolic relationships with the external world.

During the intuitive stage (ages 4–7), children become interested in games with rules, structured situations, and social interactions with others. Gradually types of rules move from sensorimotor to collective, in that rules initially accepted because they lent structure and reputation later become accepted because of social constraints and group demands. Codification of rules appears about age 11 or 12, when competitive games become the norm.

Berlyne advocated an autotelic approach. His attempts to reduce all definitions of play to a few key concepts produced four recurrent motifs:

1. Playful activities are carried on "for their own sake" or for the sake of "pleasure." They contrast with serious activities, which deal with bodily needs or external threats, or otherwise achieve specifiable, practical ends. He coined the phrase "telic behavior" to describe this distinction in purpose.
2. Many writers stress the "unreality" or "quasi-reality" of play. "Reality" presumably refers to the forms of interaction between the organism and its environment that occupy most of its waking hours.
3. Several authorities have noted the mixture of "tension" and unpleasant excitement in play, and attach importance to it.
4. The final element is the reduction of arousal, relaxation of tension, and relief from conflict that occur in the course of play.

Day developed a taxonomy that includes five types of play and argued that overt characteristics do not always distinguish these types. Instead, they differ mainly in their source and telicity (goal). The five types are as follows:

1. *Exploratory Play.* Exploratory play is motivated by uncertainty concerning objects and events in the environment. It occurs generally as a reaction to novelty or complexity in the environment. The goal of exploratory play is the acquisition of information. The affect during play is pleasure (autotelic play).
2. *Creative Play.* Creative play is a more complex manifestation of exploratory play and requires the ability to symbolize as well as familiarity with the superficial or physical characteristics of the stimulus (toy). There is greater tension during creative play and the goal shifts to the maximization of hedonic pleasure (autotelic play).
3. *Diversive Play.* Diversive play is seen as aimless interaction with the environment in general when boredom has set in. It may take many forms, such as aimless locomotion or alternation among different activities or locations. A common expression of diversive play is the continuous switching of channels on a television set with a remote control (autotelic play).
4. *Mimetic Play.* Mimetic play tends to be repetitious, structured, and symbolic. It is the only form of play that can be considered exotelic because its purpose is the enhancement of competence and mastery. Often the activity is not necessarily considered play, as exemplified by practicing a musical instrument or a sport (exotelic play).
5. *Cathartic Play.* Therapeutic in goal, cathartic play may take any form or shape. Although intrinsic in the sense of reducing arousal, it does not seem to be associated with positive hedonic affect or pleasure (mixed autotelic and exotelic play).

Child therapists often use cathartic play as a treatment modality. They argue that children are generally unable to express their discontent and anxiety verbally, but when allowed to express these in an unstructured milieu rich in fantasy-producing material such as toys, will work through their feelings toward appropriate growth and maturation. Thus, they allow children the opportunity to play and enhance competence while relieving stress. In this case, play is both autotelic and exotelic.

Playfulness

Probably a better approach to the study of play is to avoid the term altogether and to posit that playfulness, together with workfulness, is a condition existing in all acts, whether jobs, games, or schooling. Playfulness is that portion of the activity that is intrinsically rewarding (autotelic) and workfulness is the exotelic portion. Over time and repetition predictability sets in, playfulness ebbs, and activities lose their autotelicity and become workful. Day has taken this approach and devised a questionnaire that measures the proportion of playfulness in different activities, including occupations and games, and measures change in proportions of each over time. High levels of playfulness enhance motivation to participate in these activities, but when autolicity wanes, activities become boring and, unless the extrinsic reward is increased, are often abandoned.

PLAY THERAPY

The term *play therapy* is employed in at least two different ways to describe child psychotherapy. First, the term sometimes refers to particular psychotherapy approaches that centrally emphasize children's play as a means of therapeutic communication and as a modality through which children's problems can be solved (e.g., Bromfield, 1992; Ciottone & Madonna, 1996; Kaduson & Schaefer, 1997; McMahon, 1992; Schaefer, 1993; Singer, 1993). Second, the term *play therapy* is employed more generally to describe individual child psychotherapy. That usage occurs because virtually all therapies rely on children's play at least as a mode of communication (Johnson, Rasbury, & Siegel, 1997), although they differ in whether play is considered central or relatively incidental to the process of change. Such differences of opinion depend upon therapists' theoretical orientations and upon the children's ages and their problems.

Various forms of play are useful in child psychotherapy. Even simple *practice play,* (e.g., bouncing a ball) can help a

child relax and become comfortable with the therapist. In addition, *games with rules* (e.g., checkers) can teach children about fair play (e.g., Gardner, 1993). *Symbolic* or *pretend play,* however, is especially important for psychotherapy, because such play expresses children's experiences beyond their limited capacity to verbally explain themselves.

Symbolic play entails engaging in one activity with one object for the purpose of representing a different activity and a different object. Thus, a child might jump about while holding a broomstick, playing "horsie," in order to represent a cowboy riding a horse. Symbolic play can involve toys (e.g., dolls or action figures) or sociodramatic scenes in which children join together to enact stories. Symbolic play represents and communicates children's personal viewpoints about real events as well as their wishes, fears, and other personal reactions to those events (e.g., Bretherton, 1989; Ciottone & Madonna, 1996; Johnson et al., 1997; Schaefer, 1993). For example, children would not play "horsie" unless they were familiar with the possibility of riding horses and had some feelings about this activity. In fact, researchers find that children are especially likely to symbolically enact events and wishes that have aroused their anxiety as well as their desire (Watson, 1994). Symbolic play is "often so revealing of the child's otherwise hidden wishes and percepts (that it) can open the inner world of the child to the therapist" (Coppollilo, 1987, p. 228).

Beyond providing therapists with information about children's internal lives, therapeutic orientations that place a very central value on play propose that engaging in symbolic play is inherently "curative." Symbolic play sometimes provides children with an avenue to actually resolve the anxiety and dilemmas that are expressed symbolically (Bretherton, 1989; Ciottone & Madonna, 1996; Schaefer, 1993; Watson, 1994). For example, play might provide relief by allowing a symbolic expression of experiences that would be too threatening to express directly (Johnson et al., 1997; Watson, 1994). Moreover, while playing, children are "in charge," and they experience the relief of being active and in control, in contrast to the powerlessness they ordinarily experience in threatening situations (Copollilo, 1987; Erikson, 1977; Sarnoff, 1976; Schaefer, 1993). Some authors propose that children construct new ways of coping with their dilemmas when they miniaturize or "model" dilemmas symbolically (e.g., Erikson, 1964, 1977; Watson, 1994).

Client-centered and existential therapists permit considerable uninterrupted play in therapy (Axline, 1947; Ellinwood & Raskin, 1993; Moustakas, 1953). These therapists presume that play is therapeutic insofar as it occurs in the context of an accepting, clarifying, and confidential therapeutic relationship. Such relationships allows children to fully symbolize their subjective experiences and impressions. Although not necessarily accepting this unique emphasis on the curative alliance between children and therapists, all approaches to child therapy do presume that the quality of the relationship is important (Shirk & Saiz, 1992).

In contrast to emphasizing the benefits of unimpeded play, other therapists actively intervene while the child is playing. For example, psychodynamic therapists intervene by providing children with interpretations about the meaning of the wishes, fears, and ways of coping that are represented symbolically (Copollilo, 1987; Singer, 1993). Such interpretations are intended to help children to understand and express their experiences consciously, not only symbolically. Increasingly conscious understanding can provide for increasingly adaptive ways of coping. Moreover, some therapists emphasize the need to explicitly interpret connections between real, traumatizing events and the repetitive play through which some children symbolize such traumas (Silvern, Karyl, & Landis, 1995).

Other therapeutic approaches grant play a somewhat incidental role, rather than a central one. For example, play can be an adjunct to cognitive-behavioral therapy that has a primary goal of teaching new cognitions about the social world and new ways of coping with emotions and social interactions. Kendall and Braswell (1993) suggested that playing out problematic social interactions can reveal children's perspectives and their problematic cognitions that should be corrected. Knell (1993) proposed a cognitive-behavioral approach to play therapy in which therapists structure the child's play, which is integrated into educational techniques such as modeling, role-playing, and reinforcement of adaptive thoughts and behavior.

Whatever the particular approach, play therapy is ordinarily conducted in a therapeutic playroom. To facilitate the therapy process, the playroom is ideally equipped with materials that are suitable for children of different ages and backgrounds. Materials should also be sufficiently varied to encourage enacting diverse themes and personal issues (Johnson et al., 1997). Unstructured materials, including sand, water, and clay, are intended to foster maximum freedom of self-expression. Structured materials such as cars or puppets are often introduced to elicit play about particular themes that deal with feelings, attitudes, and conflicts in family or peer relationships (Johnson et al., 1997). For example, some therapists introduce two doll houses for children who are adjusting to having two homes after adoption or divorce (e.g., Kuhli, 1993). Similarly, toy medical equipment might be introduced to children who are facing a medical procedure (Oremland, 1993).

Instead of focusing on toys, many therapists have adopted Gardner's (1971, 1993b) "mutual storytelling" technique. The therapist begins to tell a story that raises a therapeutic issue; the client finishes the story while the therapist suggests adaptive outcomes.

Although play therapy has traditionally been employed with general emotional and behavioral disorders, in recent years several specialized approaches have been developed for particular life problems. For example, specialized approaches have been developed for children who have been sexually abused (Ciottone & Madonna, 1996; McMahon, 1992), children who have been otherwise traumatized (Sil-

vern et al., 1995; Webb, 1991), children who are undergoing frightening medical procedures (Oremland, 1993), and children with developmental or physical handicaps (Hellendoorn, van der Kooij, & Sutton-Smith, 1994).

Recently, play has been extended beyond its traditional role in individual psychotherapy to other treatment modalities. For example, play techniques have been integrated into family therapy (Gil, 1994). Additionally, school-based programs train socially disadvantaged children to engage in symbolic play with the intention of preventing developmental, psychological, and school problems (Hellendoorn et al., 1994). Play has also been integrated into many parent training approaches (Foote, Eyberg, & Schuhmann, 1998; Strayhorn, 1994). Although the goals of parent training are typically to improve childrearing and discipline, empirical findings have revealed that it is more effective to initially establish playful interactions between children and parents than to immediately focus on discipline skills (Foote et al., 1998).

Since there are many approaches to child psychotherapy, it is important for parents to inquire about therapists' orientations and practices. By itself, the term *play therapy* reveals little about the specific characteristics of a particular therapist's treatment.

POLICE PSYCHOLOGY

The origins of American police psychology have been traced back to at least 1916, when Terman attempted to use the then-current Stanford-Binet test, First Edition, to identify "good" prospective police officers in California. His research indicated officers are likely to require a minimum IQ of 80 to adequately perform job duties. Few published contributions to police psychology ensued until the mid-twentieth century, when psychologists began to offer services to various local, state, and federal law enforcement organizations.

Precipitated by the advancements of police psychologists in the 1960s and 1970s, especially those of Reiser (1972) and his associates, a rapidly growing interest developed in providing psychological services to law enforcement agencies. Given the considerable growth during the past dozen years police psychology is likely to be one of the principal directions of future forensic and clinical psychological practice.

What Is It?

Psychological services for law enforcement frequently involve new applications of traditional clinical and industrial-organizational psychological services. Police psychology is a specialty subsection of forensic psychology. Police psychology is the interface between the behavioral sciences and law enforcement.

Police psychological services are generally grouped into two categories: employee services and organizational services. Employee-oriented services generally recognize the employee as the client. Employee assistance services include counseling and assessment requested by the employee. Organizational services recognize the agency as the client and include preemployment psychological evaluations, fitness-for-duty evaluations, and management consultations. Hybrid services (such as crisis counseling) have developed which are both employee-oriented and organizational in nature. Crisis counseling may be requested and organized by the agency, but agency administrators have limited access to the process (Super, 1999). Police psychologists may provide services as agency employees or as contractual consultants, depending on the specific needs and resources of the agency.

Assessment

Approximately one third of police psychologists assist in the selection of recruits for police training and in the selection of trainee graduates for positions in law enforcement. Psychologists conduct fitness-for-duty evaluations of police officers who have been in stressful or physically debilitating interactions while on the job. Psychologists have also participated in the assessment procedures for advanced placements and promotions within the law enforcement community (Blau, 1994).

Psychological assessment techniques, including interviews, objective personality tests, intelligence tests, and in vitro video-based assessment have been used to assist in the selection of law enforcement officers, corrections officers, and special police team members (SWAT, hostage negotiation, undercover agents, child protection specialists, and so forth). The three approaches commonly used in preemployment psychological evaluation include: (1) selection of the best suited applicants; (2) screening out of undesirable applicants; or (3) a combination of the two (Blau, 1994; Super, 1999).

Intervention

Psychologists provide therapeutic services for police officers who are under stress, such as grief counseling for police officers and families. The need for counseling may stem from officers who are injured or killed in the line of duty. Police psychologists provide family counseling, counseling services for the children of police officers, and drug and alcohol counseling. Police psychologists assist in establishing peer counseling teams within the law enforcement agency (Kurke & Scrivner, 1996). Some psychologists offer psychoeducational evaluations for officers' children to address issues that may peripherally affect the officer's ability to discharge sworn duties.

Operations. Psychologists may be requested to provide operational services, including investigative hypnosis, investigative strategies when working with mentally disturbed suspects, hostage negotiation, and offender psychological profiling (Blau, 1994; Reese & Solomon, 1996). Although the above services are frequently viewed by laypersons as being at the core of what police psychologists do, these types of services generally represent a small part of professional activity.

Training. Psychologists provide training in police academies on such topics as offenders, stress recognition and prevention, proper methods of addressing irate citizens' complaints, cultural diversity, interviewing techniques, interpersonal skills, effective communication, impulse control, suicide prevention and intervention, and group behavior. Psychologists provide continuing education for police officers who must earn a specified number of credits every several years to maintain their sworn status. Continuing education topics may range from the psychology of driving to stress inoculation.

Strategic Planning

Generally, law enforcement has been reactive rather than proactive to crime. Modern law enforcement administrators are becoming increasingly more proactive by attempting to address prospective community needs, employing new applications of psychological services, and attempting to address changing community needs. This is at the heart of strategic planning. Psychologists, primarily industrial

and organizational psychologists, have been providing strategic planning consultations to police management with increasingly more regularity during the mid and late 1990s. Sensitivity and restraint training are areas that have recently been explored.

Research

One of the most important and most overlooked contributions by police psychologists is research involving the development of local norms, base rates, and predictive effectiveness (Super, 1999). Project funding has become more available as law enforcement administrators become more aware of the potential costs and benefits of research (Blau, 1994).

Why Is This Developing Now?

Police departments are currently being pressed to acquire accreditation. Accreditation is one method of demonstrating an agency's efficiency and modernization. As of 1999, the Commission on Accreditation for Law Enforcement Agencies (CALEA) has accredited 457 local agencies throughout the United States. There are approximately 17,000 local police agencies in the United States. Many of these will seek accreditation to participate in lower-cost risk management insurance plans. Accreditation requires departments to provide various psychological services, including preemployment psychological assessment, fitness-for-duty assessment, and assessment for hostage negotiations and SWAT team applicants. In the near future, accreditation guidelines are likely to require the availability of psychologists, on staff or as consultants, to respond to postcritical incident stress situations.

One of the agency administrator's greatest incentives for seeking psychological services is to decrease the probability of costly litigation against the department. Psychologists are helpful in selecting those people who will do the best possible job as law enforcement officers. Ongoing counseling and training by psychologists help those already working to maintain job skills and emotional stability in a stressful work setting.

What's Next?

Division 18 (Public Service) of the American Psychological Association (APA) has a Police Psychology and Public Safety subsection. Starting in about 1989 with 20 or so members, in 1999 there were approximately 252 members, including three fellows and 22 students in this subsection. Standards for preemployment psychological evaluations and fitness-for-duty evaluations have been developed and are under ongoing revision as new techniques emerge and as new applications of psychology to law enforcement arise. Several graduate institutions have begun to offer courses in police psychology.

POSTMODERNISM

Postmodern themes were discussed within architecture, literary criticism, and sociology in the United States in the 1950s and 1960s. French philosophers addressed postmodernity during the 1970s. Jean-Francois Lyotard has analyzed the status of knowledge in a postmodern age, in particular with respect to legitimation; Michael Foucault has addressed the webs of power and knowledge in historical studies; Jean Baudrillard focused on fascination, seduction, and the media's creating of a hyperreality of simulacra; Jacques Derrida has addressed language and deconstruction; and Jacques Lacan has reinterpreted the psychoanalytic unconscious. In the United States, Jameson has analyzed postmodernism as the logic of late capitalism, and Rorty has developed a neopragmatic approach to postmodernity.

Meanings of Postmodernism

The very term *postmodern* is ambiguous. It may be helpful to discern at least three meanings: postmodernity as referring to a postmodern age; postmodernism as referring to the cultural expression of a postmodern age; and postmodern thought, or discourse, as referring to philosophical reflection on a postmodern age and culture.

Postmodernity refers to an age that has lost the Enlightenment belief in progress and emancipation through more knowledge and scientific research. There is a change from a mechanical, metallurgic production to an informa-

tion industry, and from production to consumption as the main focus of the economy. It is an age in which the multiple perspectives of the new media tend to dissolve any sharp line between reality and fantasy, undermining belief in an objective reality.

Postmodernism as a cultural expression encompasses art as collage and pastiche, the pop art of Andy Warhol's consumer goods, Las Vegas-style architecture, the media's dissolution of the distinction between reality and image, and the hectic change of perspectives in the rock videos. Also focal are the labyrinthine themes of Borge's stories and the caricatures of the interpretation mania of the modern search for meaning in the novels of Umberto Eco.

Postmodern thought replaces a conception of a reality independent of the observer with notions of language as actually constituting the structures of a perspectival social reality. The modern dichotomy of an objective reality distinct from subjective images is breaking down, and being replaced by a hyperreality of self-referential signs. There is a critique of the modernist search for foundational forms and belief in a linear progress through the acquisition of knowledge.

Psychology in a Postmodern Condition

Human beings were in the center of the Age of Enlightenment. The modern science of psychology was founded on a conception of individual subjects, with internal souls and later internal psychic apparatuses. In a postmodern age, man is decentered, as the individual subject is dissolved into linguistic structures and ensembles of relations. The question arises as to the status of psychology as a science of the individual when the individual has been dethroned from the center of the world. There have been few discussions among psychologists on the consequences of a postmodern culture. Three possible implications of a postmodern approach to psychology are outlined here.

1. The very conception of a psychological science may be so rooted in modernist assumptions that it becomes difficult to understand men and women in a postmodern culture. Other disciplines, such as anthropology, have been more sensitive to the situatedness of human activity in a cultural context.
2. At the other extreme, contemporary psychology could be seen as a postmodern conceptual collage—a pastiche of recycled ideas and methods borrowed from other fields and combined according to the most recent consumer demands of a mass culture. With an extreme adaptability and flexibility, psychology does seem able to move—amoeba-like—into whatever niche opens in the markets for therapy and self-realization, as well as for selection and control of personnel.
3. A third position would involve a psychology that faces the rootedness of human existence in specific historical and cultural situations, and opens new vistas for psychology.

Implications of a postmodern discourse for the science and profession of psychology may be divided into five areas:

Knowledge and Research. A recognition of the heterogeneous and noncommensurable contexts of the everyday world involves a loss of hegemony for formalized experimental and statistical research methods. There is an acceptance of diverse quantitative and qualitative ways of producing knowledge, with a move from knowledge as abstract, objective, and universal to knowledge as ecologically valid, socially useful, and locally situated. Narrative, hermeneutical, and deconstructive approaches are included. Conversation and social practice become the contexts in which the validity of knowledge is negotiated and ascertained.

Professional Knowledge. The professional practice of psychologists is regarded as an important generator of psychological knowledge. While generally discarded by academic psychology, the insights produced by these practices are, however, in line with philosophical analyses of knowledge in a postmodern age, given that they focus on local and narrative knowledge, on the heterogeneous and linguistic knowledge of the everyday world, and on validation through practice. This does not imply a practice devoid of theory, but involves a shift in the focus of theorizing in psychology—from the interior of the individual to the relation of human beings to their world.

Systemic Therapy. The professional field where the implications of a postmodern linguistic shift have been most explicitly taken up is systemic therapy. There is a shift from studying the psyche of the individual self to studying the family as a linguistic system. Pathology is no longer seen as residing in consciousness, nor in the unconscious, but in the structures of language. Indeed the very term "psychotherapist" seems to be inadequate, for the therapist does not attempt to heal some interior "psyche," but works with language and, as a master of conversation, heals with words.

Deconstructing Social Psychology. Ian Parker and John Shotter have attempted a deconstructing of social psychology. They follow Derrida, Foucault, and Lacan in looking at the internal contradictions of these texts; analyzing their social formation; uncovering the power relations at work; and bringing forth the voices not expressed, such as the feminist work on the social construction of gender.

Social Constructionism. Ken Gergen has developed a social constructionism that rejects a substantial conception of the self and replaces the individual with the relationship as the locus of knowledge. He emphasizes the social construction of personal identities, focusing in particular on how communication technologies have led to a multiplicity of knowledge and a recognition of the perspectival nature of reality, and on the self as embedded in a multitude of networks.

Concluding Remarks

A postmodern psychology would involve a move from studying the cognitive mechanisms of an internal psychic apparatus or the inner experiences of a self-realizing self, to examining human activity in a linguistically constituted social world. The focus of interest is moved from the insides of a psychic container to being-in-the-world with other human beings. Concepts such as consciousness, the unconscious, and the psyche recede into the background, while concepts such as knowledge, language, culture, and landscape move into the foreground. A postmodern psychology will involve a move from the archaeology of a psyche to the architecture of the current cultural landscapes.

POSTTRAUMATIC STRESS DISORDER IN ADULTS

Posttraumatic Stress Disorder (PTSD) is an extreme psychobiological reaction to a psychologically traumatic event characterized by profound disturbances in cognitive, behavioral, and physiological functioning. The diagnosis is applied when an individual has experienced, witnessed, or been confronted with an event involving perceived or threatened loss of life, serious injury, or loss of physical integrity and which evoked intense fear, helplessness, or horror. The types of events that may cause PTSD include sexual or physical assault, military combat, motor vehicle accidents, major disasters, and acts of terrorism.

In the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (*DSM-IV*) symptoms of PTSD are organized under three clusters: (1) reexperiencing (e.g., intrusive thoughts, nightmares, flashbacks, and psychophysiological reactivity to reminders of the trauma); (2) avoidance and emotional numbing (e.g., avoiding stimuli associated with the trauma, and inability to experience a full range of emotions); and (3) hyperarousal (e.g., hypervigilance, exaggerated startle response, and sleep disruption). By definition, these symptoms must persist for more than one month and produce clinically significant distress or impairment.

Epidemiological studies have found that the majority of people in the general population will experience a traumatic event meeting the PTSD stressor criterion in the *DSM-IV* during their lifetime, but that only approximately 10% of those will go on to develop PTSD. However, the probability of developing the disorder depends largely on the nature and severity of the traumatic event and higher rates (i.e., closer to 25%) have been observed in select samples of individuals exposed to intense traumas involving interpersonal violence or life threat (e.g., rape survivors and combat veterans).

The relationship between trauma exposure and the development of PTSD is influenced by numerous psychosocial risk factors and individual difference variables. Psychosocial risk factors for PTSD include family history of psychiatric illness, childhood trauma or behavior problems, the presence of psychiatric symptoms prior to the trauma, inadequate social support, and an overreliance on maladaptive coping strategies. Individual difference factors also play a role in the etiology of the disorder. For example, the rate of PTSD in women, after controlling for trauma exposure, is approximately twice as high as the rate for men. In addition, personality traits associated with Introversion and Neuroticism have also been identified as liabilities for PTSD, whereas characteristics such as Hardiness appear to represent resilience factors.

Assessment and Treatment of PTSD

A comprehensive clinical assessment of PTSD should include administration of structured diagnostic interviews, self-report psychometrics, and an evaluation of trauma across the lifespan. Several structured interviews are available and the Clinician-Administered PTSD Scale for the *DSM-IV* and PTSD module of the Structured Clinical Interview for the *DSM-IV* have become standards in the field. Self-report instruments can also assist in diagnosis or provide efficient, low-cost assessment methods for research and screening purposes. Of these, several were constructed specifically for assessing PTSD (e.g., Mississippi Scale for Combat-related PTSD; PTSD Checklist; PTSD Diagnostic Scale). Others were derived from the existing items of major inventories such as the Minnesota Multiphasic Personality Inventory and the Symptom Checklist–90. Finally, instruments such as the Potential Stressful Events Interview and the Traumatic Stress Schedule are used to evaluate trauma across the lifespan.

Treatment for PTSD typically involves the use of psychotherapy, pharmacotherapy, or both. Of the psychotherapies, exposure-based approaches (e.g., systematic desensitization, flooding, prolonged exposure, imaginal and in vivo exposure, and implosive therapy) have received the most attention and empirical support to date. The common feature of each is the practice of gradually exposing the therapy client to trauma-related cues to desensitize and extinguish the accompanying conditioned emotional and physiological reactions. The therapeutic mechanism is generally conceptualized within the framework of classical conditioning; repeated exposure to trauma-related cues (e.g., trauma-related images evoked from memory) in the absence of the feared negative consequences (e.g., the trauma itself) re-

duces the conditioned fear, anxiety, and avoidance characteristics of PTSD.

A second promising category of empirically validated treatments for PTSD is cognitive restructuring therapy. Based on cognitive therapy principles, this approach is designed to identify and modify dysfunctional trauma-related beliefs and to teach specific cognitive coping skills. The therapy process may also involve tasks that include an element of exposure, such as writing or describing the trauma to uncover trauma-related cognitions.

A third psychotherapy approach is anxiety management, variously referred to as relaxation training, stress inoculation, or biofeedback training. This approach does not focus on the trauma itself, but is instead geared toward teaching an individual the requisite skills for coping with stress, often via the use of relaxation. For this reason, anxiety management is often an adjunctive treatment to trauma-focused treatments.

Pharmacotherapy for PTSD generally targets symptoms of the disorder that it shares in common with the other anxiety disorders and major depression (i.e., hyperarousal, sleep disturbance, and anhedonia) and many medications developed for the treatment of these other disorders have been used to treat PTSD. Although clinical drug trials have shown fairly modest results overall, results suggest that some individuals with PTSD may benefit greatly from pharmacotherapy. The SSRIs (including sertraline, fluoxetine, and paroxetine) are currently the medications of choice for the treatment of PTSD.

POWER: STRATEGIES AND TACTICS

Introduction

Power refers to the ability to make decisions that have an important impact and that involve others (Greenberg & Baron, 2000; McClelland, 1975; Winter, 1973). Often, power involves controlling the behavior of others, although many times other people voluntarily accept the directives of power holders and do not feel any loss of independence. In everyday language, power refers to "getting one's way" and "having clout." Many people are socialized to distrust power, to feel that only evil and manipulative individuals are interested in acquiring it, and to feel that they themselves should avoid places where powerful people congregate. In reality, and like many complex issues such as economic incentives and government-sponsored housing programs, power is like fire. It can be used for good intentions or it can be used to pursue evil goals. Power, especially the strategies and tactics for its implementation, can be viewed as a tool to be used in efforts toward the goals people set for themselves (Brislin, 1991; Buchanan & Badham, 1999; Somech & Drach-Zahavy, 2002).

Strategies reflect people's careful planning about their future in that they refer to complex sets of behaviors (e.g., resource and network development and developing the image of a winner) that will have many positive implications in their pursuit of power. Tactics, on the other hand, refer to more specific behaviors useful at a certain time and place in the pursuit of specific goals (e.g., sending up trial balloons or creating a lightning rod). Brislin (1991) developed an extensive list of both strategies and tactics useful in the acquisition and use of power. Many depend on respectful and effective working relations with other people.

The Acquisition and Use of Power: Working with Others

Power is an aspect of relationships among people, and most powerful individuals have cordial interactions with a wide variety of others. Although one image of a power holder may be a deranged monarch ordering people to commit drastic deeds, reminiscent of a bad Hollywood movie influenced by Machiavelli, power holders are most often cordial people who communicate well with others (Kotter, 1982). This is especially true in a democracy, where people have various institutional supports such as the legal system, unions, and the media to complain about callous behavior emanating from leaders. Cordial relations with others are necessary because no one person has all the skills or knowledge needed to develop complex projects and to implement them. For example, imagine that two executives want to suggest the development of a new product line. They must convince power holders, necessitating communication skills. They must research the present marketplace, demanding knowledge of survey methods, finance, production, and accounting. They must make predictions about the eventual consumption of the products, demanding knowledge of distribution systems. In addition, legal concerns will be raised at many steps in the planning process. No two people can possess all this knowledge. The two will have to integrate the efforts and talents of others.

These efforts will be made much easier if the two executives know many other people who are part of a circle of acquaintances or network (Nahavandi & Malekzadeh, 1999). These others may be old classmates, members of other departments within the same organizations, people met through community activities, people met at social gatherings, and so forth. People in one's network are not necessarily friends with whom one shares confidences. Rather, people in a network are useful to each other because they

exchange favors. If people cease being useful to each other, they drop out of each other's network, although they may enter into another network relationship years later if they become mutually useful again.

The exchanges of favors occur in a manner similar to that described by Cialdini (2000). For instance, one person knows tax law. He or she exchanges a few key pieces of advice with a lawyer who knows what terms found in advertising can be considered part of the public domain. Another person is knowledgeable about the ways that senior executives want proposals presented to them. He or she can exchange this information with another in the expectation that help will be forthcoming on the design of a survey instrument to measure market demands. Similarly, people who are knowledgeable about organizational developments through their active participation in the "grapevine" can exchange information for a variety of favors.

There is a sense of obligation in the exchange of these favors: people are expected to receive and to give. If people do not return favors, they are simply dropped from network membership and find themselves out of various information loops that previously kept them informed about developments in their organizations. Network development and maintenance may seem cold and unfeeling, yet people must be able to exchange favors if they are to develop complex projects and to stay informed about news in large organizations. Many power holders know hundreds of people with whom they can exchange favors, but they cannot become deeply involved in the emotional lives of all them. Becoming comfortable with network development is one of the necessities as people become more sophisticated about the nature of power in decision making.

Becoming More Sophisticated

Some people learn about power as part of their socialization, for instance, when they see their lawyer or politician parents participating in networks, exchanging favors, developing complex plans, and working on their strategies and tactics. Others do not have access to the application of power when they are young and must learn its techniques as adults. One way to become more sophisticated is to participate in voluntary community activities. In addition to developing a network, people can observe the processes of coalition formation, impactful communication of ideas, creation of a winning image, and so forth (Brislin, 1991). A further possibility is to obtain a seat on the community activity's budget committee. No matter what proposal is put forth for the use of money, some people will invariably prefer another use. In observing how successful people use skills, strategies, and tactics to advance their preferred plans, careful observers can learn a great deal about the use of power. They can also learn that the most sophisticated approach is not to view power as an end in itself. Rather, power should be looked on as a tool to be used in compassionate and intelligent leadership.

PRECOCIOUS DEVELOPMENT

Precocity refers to an earlier than expected maturation level. The term is often used to refer to untimely ripeness or premature fruiting. A child who is described as precocious has developed earlier and at an accelerated rate when compared to other children of the same age.

Early development can be general or specific in its manifestation. General precocity refers to a child advanced in numerous areas: physical, intellectual, and social. Specific precocity is more often the case and this typically does not present any adverse conditions for the child. However, precocity symptomatic of biological untimeliness is often pathological in that the biological patterns are highly regulated by genetic composition. Any deviations in biological development tend to produce distortions in physical structure. Precocious puberty, by definition, occurs in females before age 8 and in males at age 9 or earlier. Females who display precocious puberty develop pubic hair at an early age. In addition, breast enlargement and contour, increased ovarian and uterine volume, menses at age 9 or younger, and advanced bone age are reported. Males who display precocious puberty show signs of hirsutism or virilization and increased testicular volume (Della Manna, Setian, Damiani, Kuperman, & Dichtchekenian, 2002). Precocious

puberty occurs more frequently in the female population at a 10:1 female-to-male ratio. The estimated rate of occurrence in the overall population of children is between 1:5,000 and 1:10,000. (Partsch & Sippell, 2001)

Recent studies have suggested that nutrition and body composition may influence the development of reproductive competence in mammals. Witchel, Arslanian, & Lee (1999) reported no significant relationships between circulating gonadotropin and leptin concentrations. This is important as prior assumptions held that leptin concentrations communicated nutritional status to the neuroendrocrine reproductive axis (Heger, Partsch, Peter, Blum, Kiess, & Sippell, 1999). Gonadotropin-releasing hormone (GnRH) is linked to precocious anatomical development in males and females. GnRH agonist treatment remains controversial, although there is some attempt to standardize treatment protocols (Partsch & Sippell, 2002).

Central nervous system (CNS) abnormalities have also been linked to precocious sexual development. CNS abnormalities include tumors either specific to or with secondary effects on endocrine function. Children with neurodevelopmental disabilities are more at risk for premature sexual development when compared to children without a neurodevelopmental disability (Siddiqi, Van Dyke, Donohue, & McBrier, 1999); this finding has been reported for Williams' syndrome (Cherniske, Sadler, Schwartz, Carpenter, & Pober, 1999). An interesting case study involving monozygotic twin females both with neurofibromatosis type 1 (nf1) found that the sister with optic pathway glioma developed precocious puberty, but the sister without optic pathway glioma did not (Kelly, Sproul, Heurta, & Rogol, 1999). While precocious puberty is often found in neurofibromatosis type 1 patients, it is almost always associated with optic pathway glioma.

Meas et al. (2002) investigated a somewhat paradoxical hypothesis that intrauterine undernutrition may predispose females to serious endocrine consequences that include precocious pubarche and functional ovarian hyperandrogenism. Their study did find that precocious pubarche may be associated with future functional ovarian hyperandrogenism. However, a link between functional ovarian hyperandrogenism and intrauterine undernutrition was not demonstrated.

Another type of specific biological precocity involves premature "old age" in which the young sufferers actually die from symptoms of old age: rapid deterioration of the body and its organs, and so on. Werner syndrome (WS) is a human premature aging disorder characterized by chromosomal instability. WS, a rare autosomal recessive disorder, also produces other age-related diseases.

Precocity of cognitive functions has been reported in the literature for centuries. For example, J. S. Mill is said to have learned Greek by the age of 3! However, there is a dearth of scientific literature to support the anecdotal character of this precocious cognitive development.

While precocious puberty and aging are more clearly biologically traced, it is difficult to discern whether precocious cognitive development is a result of biological factors, environmental influence, or an interactional effect between the two.

PREJUDICE AND DISCRIMINATION

Although often employed interchangeably by lay persons and the media, the terms *prejudice* and *discrimination* possess distinct meanings for most social scientists. The former denotes the possession of *negative attitudes* of a particular kind regarding members of a specific group or category; the

latter is the term applied to the *negative actions* that result from prejudicial attitudes and that are directed against the targets or victims of prejudice. Someone who is prejudiced may, in certain situations, practice discrimination.

More specifically, social scientists view prejudice as the possession of negative attitudes targeted at members of some particular group (religious, racial, ethnic, political)—attitudes that give rise to negative or unfavorable evaluations of individuals seen as belonging to that group.

As an attitude, prejudice is seen as having a tripartite nature, comprising cognitive, affective, and behavioral components. A person's beliefs and expectations regarding a particular group constitute the cognitive component of the prejudicial attitude. The term *stereotypes* has come to designate networks or clusters of such beliefs and expectations. The basis of all stereotypes is that all those who belong to a specific category or group—ethnic, religious, racial, political, or any other classification—manifest similar behaviors and possess similar attitudes. The widespread application of stereotypes largely ignores human differences and individual differences.

Individuals who are prejudiced against specific groups will tend to experience intense negative feelings when they come into contact with these groups, either directly or indirectly. The affective component of the prejudicial attitude comes into play here, with profound negative emotional feelings tending to accompany cognitive reactions to objects of prejudice.

The behavioral component of prejudice has engendered the most research interest. Here the concern is the tendency of prejudiced individuals to act in a negative manner towards targets of their prejudice. When such tendencies become manifest in overt behavior, discrimination is said to occur. Numerous constraints upon behavior operate in everyday situations to prevent prejudicial feelings from being transformed into discriminatory behavior. If such obstacles are not present in a given instance, however, the prejudicial thought or tendency may find expression in the behavioral act, which may vary in intensity from the lowest level, mere social avoidance, to acts of extreme violence or even genocide.

The attitudinal nature of prejudice has generated measurement research modeled after much of the attitude literature. The cognitive, affective, and behavioral components of prejudice have all been the subject of research directed at assessing the nature and extent of prejudice in the population at large. The cognitive or belief component of prejudice, the assessment of stereotypes, is generally tapped through a trait-selection procedure. Individuals are given a list of ethnic, religious, racial, and political categories and a list of traits, and are asked to note which traits are associated with which group(s). Information on the affective or feeling component of prejudice is generally derived through the use of attitude scales engineered to measure the level of an individual's positive or negative feelings toward specific groups.

The *social distance scale* is an important tool in research into the behavioral component of prejudice. Subjects are presented with a series of hypothetical relationships between themselves and members of specific groups. The series of items represents increasing levels of closeness or intimacy between respondents and members of various groups (ranging from residing in the same country at the lowest level to intermarriage at the highest level), with the subjects being asked to indicate, for a given group, their willingness to accept individuals from that group into a given level of intimacy.

PRESCRIPTION PRIVILEGES

In March 2002, Governor Gary Johnson of New Mexico signed a law authorizing prescription privileges for properly trained psychologists. "Properly trained" is defined as completing at least 450 hours of coursework, completing a 400 hour/100 patient practicum under physician supervision, and passing a national certification examination. The academic component includes courses in psychopharmacology, neuroanatomy, neurophysiology, clinical pharmacology, pharmacology, pathophysiology, pharmacotherapeutics, pharmacoepidemiology, and physical and lab assessment. Following the passing of the national exam, psychologists licensed to practice in New Mexico become eligible for a two-year license permitting practice under the supervision of a physician. At the end of the two years, following physician approval and a peer review of the prescribing records, the psychologist can apply to practice independently and is expected to maintain a collaborative relationship with the patient's health care practitioner (American Psychological Association Online, 2002).

In addition to New Mexico, psychologists on Guam were able to obtain prescription privileges in 1999. A number of other states have pending legislation on prescription privileges. In 2002 these states included Georgia, Illinois, Hawaii, and Tennessee. A number of state psychological associations have created prescription privileges task forces working for legislative actions on their proposals.

Graduate schools in several states have begun to provide psychopharmacology training, as have some private organizations. According to a recent book (Levant, Sammons, & Paige, 2003), there are currently 11 programs offering postdoctoral training in psychopharmacology, and it is estimated that over 900 psychologists have pursued such training or are in the process of doing so.

Some would argue that prescription privileges are a natural extension of present laws already on the books (e.g., in California) that "establish that psychologists should be

knowledgeable about psychopharmacological effects of populations at risk and are encouraged to seek additional education in the area of geriatric pharmacology" (Ch. 1539 of the statutes of 1990). In Hawaii, State House resolution 334-90 recommended a series of roundtable discussions dealing with Hawaii's unserved mental health needs and included "the possibility of allowing appropriately trained psychologists to prescribe psychotropic medications . . . under certain conditions."

Psychologists are not newcomers to the arena of physical interventions. Jansen and Barron (1988), in reviewing this topic, asserted that biofeedback techniques, alarm bells for bed-wetting, galvanic skin responses, and polygraph assessments are examples of physical interventions already used by psychologists. Direct involvement of physical interventions by psychologists have also included behavior management procedures with children. The authors pointed out that even though psychologists have been active in the development of physical interventions, they have been automatically excluded from prescribing medications because they are not physicians.

Meeting Society's Needs: The Public Policy Perspective

Patrick DeLeon has summarized the public policy issue by arguing that the essence of prescriptive authority is to ensure that Americans have access to the highest possible quality of care. In the Foreword of *Prescriptive Authority for Psychologists* (Levant, Sammons, & Paige, 2003), he suggests a model whereby "psychotropic medications are prescribed in the context of an overarching, psychologically based treatment paradigm as opposed to current psychiatric models that have an almost exclusive biological orientation" (p. xiii). He insists that the prescriptive authority agenda involves all of psychology and is an educational agenda that strives to strengthen psychologists' understanding of the workings of the human psyche. On a policy level, he argues that the U.S. health care delivery system is in need of change, and that there is an excessive time lag between the discovery of efficacious treatments and their routine use in patient care. He argues (DeLeon, Fox, & Graham, 1991) that prescriptive authority for psychologists is not only necessary but essential to meet the needs of quality care for the mentally ill and to deal with the problem of excessive medication for the elderly. Until very recently more than half of outpatient mental health visits were conducted by general medical practitioners and nursing home residents were often medicated using drugs to treat mental disorders even though most of these elderly patients were not mentally ill.

At the other end of the age continuum, there is widespread discussion among professionals and the general public as to the justification for medicating children. It has been argued that proper diagnosis is crucial in using medications for children with Attention Deficit Disorder or Attention-Deficit/Hyperactivity Disorder. However, medications may not be necessary with other psychological disorders (DeLeon, Folen, Jennings, Willis, & Wright, 1991). One policy implication raised by these authors is how parents deal with their children. It may be that the parents' inability to cope with children, rather than the child's activity level, is the primary concern. Thus, evaluating the stress level of the parent may lead to a productive course of action without necessarily subjecting children to medication. Clinical child psychologists need to know more about the efficacy of psychoactive drugs for children and about the general area of psychopharmacology.

Opposition to Prescription Privileges

No discussion on prescription privileges would be complete without citing objections to psychologists prescribing drugs. Breggin's *Toxic Psychiatry* (1991) is noteworthy in this regard. Breggin argues that the administration of drugs by psychiatrists is a political and financial issue encouraged by the "psychopharmacological complex" that "pushes biological and genetic theories, as well as drugs, on the society" (p. 408). He argues that psychiatry as a profession must discontinue its financial collaboration with drug companies and must not make inaccurate claims regarding genetic and biological causes of mental illness. Breggin insisted that love, understanding, and psychotherapy are the answers to psychiatric problems. His concerns revolve around the addictive and damaging aspects of drugs, especially if the patient has not been apprised in advance of the effects and consequences of psychotropic medications.

Breggin also takes to task psychologists who advocate prescription privileges. He notes that some psychologists have become envious of the status accorded to psychiatrists and notes that drug companies are sponsoring and funding seminars at meetings of psychologists to discuss the advantages of prescription privileges. Brown (Levant, Sammons, & Paige, 2003) discusses the opposition to prescriptive authority by noting that prescribing medications is foreign to the identity of professional psychology because psychologists have traditionally viewed themselves as dealing primarily with the mind rather than the body. She suggests that studying the impact of biological bases of behavior or the impact of behavior on biological factors is a more recent phenomenon. Also, she points out that most psychologists today perceive the profession of medicine as intimately connected with pharmacology. This association is pervasive, she suggests, even though it is a relatively recent phenomenon; only 100 years ago most medications were available over the counter, as they are in a number of other countries today.

Final Comment

The core argument against prescription privileges is that they should not be granted because they would fundamen-

tally change the nature of psychology. Many psychologists believe that prescription privileges should never be permitted because they violate the fundamental tenets of psychology. Nevertheless, a sizable majority of psychologists do believe that some patients need psychotropic medications at some time in their lives. Moreover, the Task Force on Psychologists' Use of Physical Intervention has defined the practice of psychology as including both physical and psychological interventions (Jansen & Barron, 1988). Fox (1989) pointed out that the use of such physical interventions should occur within the context of improving the quality of services, within the competence of the provider, and in the service of consumer welfare.

Psychology is a relatively young profession and changes are part of any field's development. It certainly does appear that prescription privileges will become part of the practice of psychology in the twenty-first century.

PREVENTION OF MENTAL DISORDERS

The twentieth century witnessed major advances in the diagnosis and treatment of mental disorders. However, concerted work on prevention is just beginning as we enter the twenty-first century. In response to growing awareness of the need for prevention, Congress recently charged the Institute of Medicine (IOM) to convene a Committee on Prevention of Mental Disorders.

In their report (Mrazek & Haggerty, 1994), the IOM Committee proposed that, in order to reduce the indiscriminate use of this concept, the term *prevention* be reserved for interventions administered before the onset of a clinically diagnosable disorder. By contrast, *treatment* consists of interventions designed to ameliorate or cure a mental disorder that has already developed.

Why Prevention?

The alarming prevalence rates of many mental disorders, as well as their devastating consequences for individuals and communities, require that the mental health system move beyond focusing solely on treatment and advance toward the development and implementation of preventive interventions. The Committee identified as promising targets for prevention five disorders with heavy emotional and financial costs: Conduct Disorder, Alcohol Abuse/Dependence, Schizophrenia, Alzheimer's disease, and depressive disorders. Because Major Depressive Disorder arguably poses the most widespread risk on both a national and global level and may be the most likely to be prevented first, it can serve as a model for the prevention of other disorders (Muñoz & Ying, 1993).

In the United States, 17% of adults suffer at least one episode of major depression during their lifetimes (Kessler et al., 1994). The World Health Organization reported that major depression is the number one cause of disability in the world, and—with respect to the burden of disease in the world, taking into account both disability and mortality—major depression was the fourth most important disorder in 1990 and will become the second by 2020 (Murray & Lopez, 1996). Depression has been found to cause dysfunction that is equivalent to or worse than chronic physical illness (Wells et al., 1989), and it also contributes to major causes of death, such as smoking and drinking (Schoenborn & Horm, 1993). With a problem of this magnitude, treatment is not sufficient to reduce prevalence (the total number of affected individuals); prevention of incidence (new cases) must be achieved.

Preventive Interventions for Mental Disorders

The IOM Report identified three levels of preventive interventions. *Universal preventive interventions* target an entire population group (e.g., childhood immunizations). *Selective preventive interventions* target high-risk groups within a community (e.g., home visitation for low-birth-weight children). Risk status is determined on the basis of biological, psychological, or social factors known to be associated with the onset of a disorder, rather than individual risk profiles. *Indicated preventive interventions* target individuals with early signs or symptoms of a disorder who

do not yet meet full diagnostic criteria (e.g., parent-child training for children identified as having behavioral problems). In general, the lower the cost and the fewer the possible ill effects of a preventive intervention, the more amenable it is for universal dissemination. Conversely, more costly and potentially risky or burdensome interventions should be reserved for use with individuals who have an indicated risk for the disorder.

The Nature and Scope of Prevention

Some disorders can be fully prevented by individual behavior. For example, alcohol, drug, and nicotine dependence are 100% preventable if an individual chooses not to use those substances. For other disorders, such as depression, individual strategies will reduce risk by some as yet unknown proportion. Similarly, prevention at the community level will reduce the incidence of disorders, rather than eliminating them completely. However, taken together, individual and community-level strategies can significantly lower rates of disorders. For instance, legal and other social interventions such as cigarette tax increases, antitobacco media campaigns, and laws prohibiting smoking indoors modify individual behavior and thus impact rates of smoking initiation and smoking cessation.

It is noteworthy that prevention efforts can be successful even when the causes of a disorder are poorly understood or cannot be modified directly. For instance, phenylketonuria (PKU) is a metabolic disorder resulting from genetic mutation. However, the severe mental retardation produced by PKU can be prevented via strict dietary control. Another example is the classic case of John Snow, who halted the nineteenth-century cholera epidemic in London by removing the handle of a Broad Street water pump even though the specific agent that caused cholera was not yet known. Thus, although scientists do not yet fully comprehend the complex biological and social factors that produce mental disorders such as depression, the development of effective prevention strategies is nonetheless a feasible goal.

Evidence-based prevention services require studies to test their efficacy. For example, to date four randomized controlled trials have been conducted to evaluate whether the onset of major depressive episodes (MDEs) can be prevented. The San Francisco Depression Prevention Research Project evaluated the effects of a cognitive-behavioral prevention course with a sample of 150 primary care, predominantly minority patients and found reductions in depression symptoms but not in MDE incidence rates at 12-month follow-up. A similar pattern of results was obtained in a study of 231 college freshmen using cognitive-behavioral skills training. However, two controlled studies assessing the effects of a cognitive-behavioral coping course on at-risk adolescents reported reductions in the incidence of MDEs at 12-month follow-up. Taken together, results are promising and indicate that it is possible to prevent the onset of major depressive episodes (Muñoz, Le, Clarke, & Jaycox, 2002).

Future Directions

The mental health field will progress in the area of prevention of disorders as the general health care system moves toward parity in the treatment of mental and other disorders. Screening methods to identify cases of mental disorders in primary care settings will eventually be extended to the identification of individuals at risk. As preventive interventions receive empirical support, health care systems will be held accountable for providing those shown to be efficacious. Ultimately, as these interventions become more widespread, we will begin to see measurable drops in the incidence of targeted mental disorders, with a resulting decrease in their prevalence. This will be a major achievement both from the standpoint of lowering health care costs and, more importantly, reducing human suffering.

PRIMARY MENTAL ABILITIES

One of the earliest accomplishments of the science of psychology was the objective measurement of mental abilities.

In 1904, the British psychologist Charles Spearman argued that intelligence could be characterized as being composed of a general factor (*g*) common to all meaningful activity and of specific factors (*s*) that are unique to the different tasks used to measure intelligence. Test instruments that applied the concept of general intelligence were introduced by Binet and Simon in France and by Terman in the United States. American psychologists engaged in educational and occupational selection activities found the concept of general intelligence less useful for predicting success in specific jobs or other life roles. In addition, Thorndike's work on transfer of training had suggested that the notion of generalizability of a single ability dimension was not justified.

Efforts soon began, therefore, to determine whether human abilities could be described along a parsimonious number of distinct substantive dimensions. Initial work along these lines began with the publication of T. L. Kelley's *Crossroads in the Mind of Man* (1928), which advocated the determination of group factors representing distinct skills, such as facility with numbers, facility with verbal materials, spatial relationships, speed, and memory. These efforts were also aided by advances in the methods of factor analysis that allowed the determination of multiple factors, each representing a latent construct represented by sets of independently observed variables.

Most prominently associated with these developments was L. L. Thurstone (1935), who expressed the hope that a careful scrutiny of the relations among a wide array of assessment devices, developed to reflect a given construct as purely as possible, would yield a limited number of dimensions that would reflect "the building blocks of the mind." He administered a battery of 56 simple psychological tests to a large number of children in Chicago schools and applied factor analysis to determine the latent basic ability dimensions represented by these tests. Given the procedures available at the time, he was reasonably successful in showing that fewer than 10 latent constructs were required to explain most individual differences variance in his measures. The factors obtained in this work were consequently labeled the *primary mental abilities.*

Most of the factors identified by Thurstone have been replicated subsequently in work by others. The most important factors, in order of the proportion of individual differences explained, are the following:

Verbal comprehension (*V*). This factor represents the scope of a person's passive vocabulary, and is most often measured by multiple-choice recognition vocabulary tests.

Spatial Orientation (*S*). The ability to visualize and mentally rotate abstract figures in two- or three-dimensional space. This ability is thought to be involved in understanding maps and charts and in assembling objects that require manipulation of spatial configurations. This may be a complex factor involving both visualization and the perception of spatial relationships.

Inductive Reasoning (*R* or *I*). This is the ability to determine a rule or principle from individual instances, probably involved in most human problem solving. The ability is generally measured using a number or letter series that has several embedded rules; the subject is asked to complete the series correctly.

Number (*N*). This is the ability to engage rapidly and correctly in a variety of computational operations. The most simple measure of this ability is a test checking sums for addition problems.

Word Fluency (*W*). This factor represents a person's active vocabulary and is generally measured by free recall of words according to a lexical rule.

Associative Memory (*M*). Found primarily in verbal tasks involving paired associates or list learning. It is not a general memory factor, evidence for which has not thus far been established.

Perceptual Speed (*P*). This ability involves the rapid and accurate identification of visual details, similarities, and differences. It is usually measured by letter canceling, simple stimulus, or number comparison tasks.

Other organizational schemes to characterize multiple abilities have been developed by G. H. Thompson (1948) and P. E. Vernon (1960) in England and by J. P. Guilford (1967) in the United States. The latter system actually classified tasks along a three-dimensional higher-order hierarchy in terms of content, product, and operations involved in each task, resulting in a taxonomy of as many as 120 factors, many of which remain to be operationalized.

For the purposes of educational application, L. L. Thurstone and T. G. Thurstone (1949) developed a series of tests at several difficulty levels suitable from kindergarten to high school designed to measure Thurstone's first five factors (*V, S, R, N,* and *W*). This battery was updated and revised by T. G. Thurstone in 1962. Measures of the other factors may be found in the kit of factor-referenced tests (1976) developed by the Educational Testing Service.

The primary mental abilities measures have had little use in educational practice in recent years. However, the primary abilities have experienced a revival as a useful measurement instrument for charting the course of abilities in studies of adult development (also see "Adult Intellectual Development"). A special version of the primary abilities tests particularly suitable for work with older adults has also been developed (STAMAT). Factorial invariance of six latent ability dimensions (Inductive Reasoning, Spatial Orientation, Verbal Ability, Numeric Ability, Perceptual Speed, and Verbal Memory) has been demonstrated in longitudinal samples across time and different birth cohorts (as well as across genders) (Schaie, 1996). The validity of the primary mental abilities in adults has also been examined with respect to its relation to mea-

sures of practical intelligence and subjective perception of competence, as well as to specific occupational outcomes.

PRIMARY MOTOR CORTEX AND PRIMARY SOMATIC SENSORY CORTEX

The primary motor cortex and the primary somatic sensory cortex represent two principal components of sensory motor integration implemented in the brain. The fundamental function of motor cortex is to control voluntary movements, whereas somatic sensory cortex receives and analyzes tactile, joint, and muscle sensory inputs, sometimes in relation to voluntary movement. From classical perspectives, motor cortex functions as the final cortical output for already processed movement commands, relaying signals from premotor cerebral cortical sites to the spinal cord. Similarly, somatic sensory cortex has often been viewed as a pipe to relay subcortical inputs to higher order cortical sites for further processing. Recent evidence indicates more complex and crucial roles for primary motor cortex and primary somatic sensory cortex in processing motor and somatic sensory information.

Primary Motor Cortex

In the past two decades, new concepts have emerged to explain the function and role of motor cortex in movement control. Instead of resembling an automatic "piano player" superimposed upon spinal cord output, motor cortex appears to have significant functions related to movement planning and learning. The neural substrate for these higher order functions of motor cortex likely relates to the distributed and plastic anatomical and functional organization within motor cortex.

Motor Cortical Organization

Motor cortex has three functional subdivisions, one each for the upper limb, the lower limb, and the head and neck; output from these subdivisions yields the motor commands that elaborate voluntary movement. Previous principles of motor cortex organization indicated a somatotopic pattern resembling a distorted but recognizable body shape—the homunculus—represented upon the surface of the motor cortex. A functional consequence of the homuncular arrangement could be to imply dedication of specific neural elements, such as a cortical column, to controlling one body part, perhaps a finger.

Recent evidence suggests that motor cortex does not have a regular and organized somatotopic pattern. Instead, circuits in motor cortex exhibit a widely distributed, multiple and overlapping representation of the different body parts, though there remains separation between the leg, arm, and head representations. Thus, neural circuits in motor cortex related to finger movements are intermingled and may be shared with circuits for the more proximal movements. The distributed and shared functional organization of motor cortex can provide for flexibility and enormous storage capacity.

Motor Cortex Plasticity and Cognition

Motor function has nearly infinite flexibility, ranging from the capability to learn new simple or complex tasks to recovery from central nervous system damage that might come about through changes in motor cortex internal pro-

cessing. Flexibility of motor cortex output can be influenced by behavioral or physiological context. For example, changing a posture before moving modifies somatic sensory input that can then yield differing motor cortex output. These effects may be explained by changes in central set by neural facilitation of motor cortex networks, and likely are influenced by local synaptic interactions. Limits seem to exist upon the flexibility of motor cortex representations. In normal individuals, motor cortex sites retain functionality related to the represented movements.

Possibly related to its flexible output, motor cortex has an important role in adapting and learning motor skills. Motor representations in human motor cortex exhibit modification following short-term or long-term experience, such as repeating a finger movement for a few minutes or over weeks. Learning a movement sequence changes the amount of functional activation in motor cortex or the coupling between motor cortex and target structures in the spinal cord. Motor cortex patterns also change when humans learn to associate arbitrary visual signals with already known motor skills.

Neural substrates in motor cortex may provide the basis for motor learning. Plasticity occurs between sites interconnected with internal, or horizontal, connections in motor cortex. Many of these horizontal connections exhibit short- and long-term synaptic plasticity. Blockade of motor cortical synaptic plasticity reduces behavioral manifestations of motor learning or motor cortex output shifts. The coupling of functional studies on motor cortex relationships with motor learning and the new findings on synaptic reorganization of motor cortex suggest the motor cortex does have an important role in skill acquisition.

Motor cortex also plays a role in higher-order motor functions, including cognition. Neurons in motor cortex have functional relationships with movement planning and appear to code for abstract movement features such as direction, movement goal, and target position. The activity of motor cortex can be uncoupled from observable movements or neuronal excitability occurring within motor portions of the spinal cord, such as during mental rehearsal of movements.

Primary Somatic Sensory Cortex

The primary somatic sensory cortex receives detailed sensory information about the skin, muscle, and joints that becomes segregated into anatomically distinguishable subdivisions that separately process sensation related to skin surface deformations or deep joint and muscle sensations. Each subzone has a complete "homuncular" representation of the body surface with little overlap among circuits processing somatic sensory input from nearby body parts. Somatic sensory cortex has a columnar organization, such that neurons aligned vertically process the same type of somatic sensory stimulus impinging on the same point of the body surface, converting raw sensory data into perceptions of stimulus velocity, texture, and form. Somatic sensory cortex relays locally processed information laterally to other body part representations within somatic sensory cortex, and to motor and association areas of the cerebral cortex.

The body representation in somatic sensory cortex exhibits plasticity. Nerve injury or pathological changes deprive cortical zones of crucial inputs; this can yield unresponsive zones, but more commonly causes expansion of neighboring body representations into the denervated cortical territory. Analogous reorganization occurs in relation to experience such as the repetition of sensory-based actions.

In summary, primary motor cortex and primary somatic sensory cortex have complete and complex representations of the body. These two areas represent the major cortical output and input structures for sensory motor integration. Motor and somatic sensory cortex do not function as simple purveyors of already processed motor commands (motor cortex) or of unprocessed somatic sensory inputs. They have key roles as higher-order information processing structures and participate in many aspects of sensory motor integration.

PRIMARY PREVENTION OF PSYCHOPATHOLOGY

Primary prevention involves efforts to reduce the future incidence of emotional disorders and mental conditions in populations of persons not yet affected. The efforts are proactive. Primary prevention sometimes is directed at high-risk groups, or at groups approaching high-risk situations or potential life crises. Programs in primary prevention may involve the reduction of organic factors contributing to psychopathology, efforts to reduce avoidable stress, the building of competencies and coping skills, the development of improved self-esteem, and the enhancement of support networks and groups.

The logic of investing in efforts at primary prevention is supported in several ways. For example, the incredible imbalance between the number of people suffering emotional distress and those with mental disorders makes it impossible for individual interventionists to reach those needing help, and this gap is impossible to bridge.

Most of the enormous improvement in the health and increasing longevity of members of our society has come about as a result of the successful application of the methods of primary prevention within the field of public health. Public health prevention methods involve "finding the noxious agent" and taking steps to eliminate or neutralize it, or "strengthening the host."

During the first enthusiasm for the application of public health methods in the field of mental disorder, it seemed just a matter of time until these "mental illnesses" could also be brought under control and eliminated. However, as time has passed, it is gradually becoming apparent that most of the so-called mental illnesses may not have a specific and unique cause.

A high level of stress-causing conditions (e.g., powerlessness, unemployment, sexism, marital disruption, loss of support systems) can cause any of several patterns of emotional disruption (e.g., depression, alcoholism, anxiety, hypertension). In brief, there is a nonspecific relation between causes and consequences.

If our purpose is to reduce the incidence of the different conditions or compulsive lifestyles we refer to as mental disorders, is there any way to think about organizing prevention efforts? The following formula may be helpful:

$$\text{Incidence} = \frac{\text{Organic factors} + \text{Stress}}{\text{Competence} + \text{Self-esteem} + \text{Support networks}}$$

To succeed in preventive efforts is to reduce the incidence of the various forms of emotional disturbance. There are several strategies for accomplishing that purpose. The first is to prevent, minimize, or reduce the number of organic factors. The more an organic factor can be reduced or eliminated, the smaller the resulting incidence will be. Specific examples are as follows:

1. Reduction of the amount of brain damage resulting from lead poisoning or from accidents reduces the resulting mental conditions.
2. Prevention of damaged genes from developing into damaged individuals (after amniocentesis, aborting a fetus with chromosomal abnormalities) prevents the birth of a mentally impaired or brain-damaged infant.
3. Provision of medication to reduce hypertension lowers the incidence of brain injury resulting from strokes.
4. Improvement of the circulation of blood to the brain reduces the rate of later cerebral arteriosclerosis.

A second strategy involves the reduction of stress. Here relationships become more complex. Stress takes many forms. Reducing stress requires changes in the physical and social environment. Environmental stress situations involve a whole complex of interacting variables. Some forms of social stress are a product of deeply ingrained cultural values and ways of life not easily susceptible to change. Stress may result from low self-esteem that becomes a kind of self-fulfilling prophecy. Women and members of ethnic minorities, who learn from earliest childhood that their sex or race is seen as inferior, grow up with lower self-esteem that may be exceedingly difficult to change. Preventive efforts take the form of public education, changes in the mass media, and the reshaping of pervasive value systems. Such efforts encounter the angry resistance of the power forces that get real benefit from the values being criticized.

An area of major research investigation in recent years has been the relationship between stressful life events and the onset of both physical illness and mental disturbance. Studies report correlations between severity of life stresses and the probability of the appearance of specific illnesses in the future. Statistically significant relationships have been found between the stresses of life change and diseases such as tuberculosis, heart attacks, accidents, leukemia, and diabetes. High life stress has been associated repeatedly with subsequent mental and emotional disturbances. Being part of a strong support network reduces the risk of exposure to stress.

The model described by the formula obviously has shortcomings. Often intervention results in changes in all areas. For example, training in a sport may involve regular practice with resulting improvement in physical coordination, bodily health, musculature, circulation, and a sense of physical well-being. At the same time, the subject may experience a reduction of stress as he or she burns up energy in physical activity; meanwhile, improvement in competence in performing the physical requirements of the sport may increase self-confidence and self-esteem. Thus improvement occurs at all levels.

Ultimately, many prevention efforts will require societal change through political action. For this reason, the struggle to redistribute power as a strategy for the prevention of psychopathology has only begun.

PRIMARY, SECONDARY, AND TERTIARY GAINS AND SECONDARY LOSSES

Freud defined *primary gain* as a decrease in anxiety from a defensive operation which caused a symptom. *Secondary gain* was defined as interpersonal or social advantage attained by the patient because of the illness. The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV-R*) de-

fined primary gain as the gain achieved from a conversion symptom which in turn keeps a conflict out of awareness. Secondary gain was defined as the gain achieved from the conversion symptom in avoiding a noxious activity or enabling support from the environment. Secondary gain is not a *DSM-III-R* diagnosis. Primary and secondary gains are thought to occur by unconscious mechanisms. The following is a list of possible secondary gains: gratification of dependency needs; gratification of revengeful strivings; fulfillment of need for attachment; desire of patient to prove entitlement for disability; fulfillment of need for oversolicitousness from others; avoidance of hazardous work conditions; fulfillment of need for sympathy and concern; permission to withdraw from unsatisfactory life role; need for sick role; financial rewards; acquisition of drugs; manipulation of spouse; maintenance of family status; maintenance of family love; domination of family; freedom from given socioemotional role; and contraception.

Tertiary gains are attained from a patient's illness by someone other than the patient. It is not known whether these occur at a conscious or unconscious level. The following is a list of possible tertiary gains: Collusion on the part of the significant other to focus on patient's somatic complaints; diversion of attention from existential issues (cancer/death); enjoyment of change in role for significant other; financial gain; sympathy from social network; decreased family tension; and resolution of marital difficulties.

It is not clear whether secondary gains are the same as reinforcers. It appears that operationally some are the same; the gain may be the reinforcer. Secondary gains, however, are a more unconscious motivation for the observed behaviors.

Abnormal illness-affirming states include the following *DSM-IV-R* diagnoses: somatoform disorders (Conversion Disorder, Hypochondriasis, Somatization Disorder, Pain Disorder); factitious disorders (including Munchausen Syndrome); and malingering. In all these diagnoses, secondary gain is thought to be responsible for the production of some or all of the patient's signs and symptoms.

Secondary losses may also result from a patient's disability. The following is a list of possible secondary losses: economic loss, loss of opportunity to relate to others through work, loss of family life, loss of recreational activities, loss of comfortable and clearly defined role, loss of respect and attention from those in helping roles, loss of community approval, social stigma of being chronically disabled, guilt over disability, negative sanctions from family, and loss of social support. Patients act in spite of these losses even though the secondary losses far outweigh the secondary gains. This problem with the economy of secondary gains and losses is a direct challenge to the integrity of the secondary gain concept.

Secondary gain is often incorrectly equated with malingering. The term has also been equated with financial rewards associated with disability, which in turn is equated with malingering. Suspicion of malingering usually interferes with treatment and development of empathy. Moreover, secondary gain issues are often used as an excuse for treatment failure. Treating professionals often ignore the concept of secondary loss and focus only on secondary gain. If all patients in a medical facility were examined for alleged secondary gains, most would be found to have one or more secondary gains; however, the identification of an apparent secondary gain does not necessarily mean that this gain has had an etiological or reinforcing effect on the illness.

PRIMARY SOMATOSENSORY CORTEX

The somatosensory cortex was defined in earlier human studies as the cortical region the stimulation of which provoked subjective somatosensory experiences. It was defined in various other mammals as the cortical region where somatosensory-evoked potentials were recorded after stimulation of the periphery. The cortical areas involved in the somatosensory processing are distributed widely in the parietal lobe, the postcentral gyrus, posterior parietal regions, and lateral regions. They form a connected network with serial (hierarchical) and parallel cortico-cortical connections. Among them, the primary somatosensory cortex (or the first somatosensory cortex [SI]) is defined as the area where the shortest-latency, evoked potentials are recorded after stimulation of the periphery. It receives direct and strongest projections from the thalamic ventrobasal complex—specific relay nuclei mainly for the dorsal column-lemniscal system that conveys innocuous somatosensory signals from the periphery.

Anatomy

The SI of primates is composed of four different cytoarchitectonic areas of Brodmann: areas 3a, 3b, 1, and 2 in the postcentral gyrus. The thalamic ventrobasal complex projects mainly to areas 3a and 3b. Sensory signals from deep tissues—muscles or joints—project mainly to area 3a, while those from the superficial tissues—skin or intra-oral mucous membrane—project mainly to area 3b. Areas 1 and 2 receive fewer projections from the thalamic ventrobasal complex and instead receive cortico-cortical projections from areas 3a and 3b and some additional projections from the thalamic association nuclei. All four cytoarchitectonic subdivisions of SI have connections to the second somatosensory cortex (SII) in the lateral regions (see Jones, 1986; Burton & Sinclair, 1996).

Somatotopic Representation of the Body Surface

It is generally accepted that the sensory cortex is characterized by topological and orderly representation of the receptor sheet. In the primary somatosensory cortex of the primate, the oral cavity, face, hand, arm, trunk, leg, and foot are represented somatotopically along the lateral-medial axis of the postcentral gyrus. Penfield and Boldrey (1937) invented a homunculus to describe such an arrangement. The somatotopic representation of the body over the cortical surface was demonstrated in various other mammals by recording evoked potentials. The cortical tissue devoted to each body-part representation is not even. That part of the body which is exaggerated differs among animals. In primates, the cortical region devoted to the representation of the oral cavity, face, hand, or foot is much larger compared to that for the trunk or proximal limbs (see Burton & Sinclair, 1996).

Hierarchical Processing in the Finger Region

Modern microelectrode techniques to record single neuronal activity in awake animals enabled scientists to analyze detailed organization of the enlarged cortical finger representation in the monkey (Burton & Sinclair, 1996). In the finger region of area 3b in the monkey, functionally unique parts of fingers (i.e., tips, ventral glabrous surfaces, and dorsal surfaces) are represented separately, forming different subdivisions of area 3b. In areas 1 and 2, progressive interphalangeal or interdigital integration takes place along the rostro-caudal axis of the postcentral gyrus; thus, receptive fields of neurons in areas 1 and 2 become larger, covering more than one phalange of a finger, or more than one finger. The interdigital integration is more remarkable in the ulnar fingers than in the radial ones. There are unique types of neurons in areas 1 and 2 with selectivity to specific features of stimulus, such as the direction of a moving stimulus; the presence of an edge or rough surface; those that are activated better or solely by the monkey's active hand movements, including reaching; or those facilitated or inhibited by attention. Diversity in the receptive field of cortical neurons was pointed out also in conjunction with a cortical column (a perpendicular array of neurons). There are a number of additional observations in favor of serial hierarchical processing.

The integration proceeds to combine information from the bilateral sides in the higher stages of hierarchical processing: A substantial number of neurons with bilateral or ipsilateral receptive fields are found in the caudalmost part (areas 2 and 5) of the postcentral finger region (Iwamura, Iriki, & Tanaka, 1994). Bilateral integration is seen also in other body parts. The bilateral receptive fields are large and the most complex types found in this gyrus. The distribution of the bilateral receptive field neurons roughly corresponds to that of callosal connections in this gyrus.

Plastic Changes in the Representation of Fingers

After extensive training to use three fingers together, there emerged in area 3b of owl monkey neurons with multidigit receptive fields, which were never seen in untrained animals (Wang, Merzenich, Sameshima, & Jenkins, 1995). Blind persons who use three fingers together to read Braille frequently misperceive which of the fingers actually touches the text. In these subjects an expansion and dislocation of SI hand representation was found by magnetic source imaging technique (Sterr et al., 1998). The representation area of fingers measured by magnetic source imaging increased in the left hand in string players, possibly as the result of extensive training (Elbert, Pantev, Weinbruch, Rockstroh, & Taub, 1995).

Attributes of Tactile Perception Represented in Cortical Activity

Cortical activities representing spatio-temporal patterns of tactile skin stimulation such as flutter-vibration, motion, direction, length, velocity of tactile stimulus, surface texture, spatial form, and so on, have been studied (see Burton & Sinclair, 1996). DiCarlo, Johnson, and Hsiao (1998) found that 94% of area 3b neurons in the finger region contained a single central excitation, as well as regions of inhibition located on one or more sides of the excitatory center. It was thus indicated that area 3b neurons act as local spatio-temporal filters and may contribute to form and texture perception.

Cortical Representation of Pain

Single-cell recordings in the monkey established that nociceptive pathways project to areas 3b and 1 of the primary somatosensory cortex. Pain has a sensory component in addition to its strong emotional component, and is processed by multiple distributed cortical loci. The SI cortex is involved in the sensory-discriminative aspect of pain, especially stimulus localization, while intensity may be coded by multiple cortical areas (see Treede, Kenshalo, Gracely, & Jones, 1999).

PRIMING

Priming is a long-term memory phenomenon that increases the efficiency of processing repeated stimuli. Most long-term memory tasks comprise three phases: (1) a study phase in which stimuli are encoded, (2) a retention interval in which an unrelated task is performed, and (3) a test phase in which memories of the encoded stimuli are retrieved. Retrieval can be measured either as a conscious recollection of the study-phase stimuli, or as a nonconscious change in processing speed, processing accuracy, or response bias accrued to the recently studied material. Retrieval tasks that require conscious and deliberate reconstruction of the study-phase experience are referred to as explicit (Schacter & Graf, 1986), direct (Richardson-Klavehn & Bjork, 1988), or declarative (Cohen & Squire, 1980). Retrieval tasks that require no reference to the study-phase experience are referred to as implicit, indirect, or procedural.

Priming memory is revealed on implicit tasks. In the test phase of a priming memory experiment, the subject is asked to perform a task that is ostensibly unrelated to the study-phase task, but in actuality, requires repeated processing of studied stimuli and new processing of unstudied stimuli. In some tasks, processing of the identical study-phase stimuli is required (identity or direct priming). In other tasks, processing of stimuli that are related to the study-phase stimuli is required (indirect priming). Priming memory is calculated as the difference in performance between repeated versus new stimuli, which reflects memory acquired in the study phase and retrieved in the test phase.

Priming is not limited to previously known items or well-known associations between items (e.g., *bird-stork*). Priming has been demonstrated using novel items such as nonsense pseudowords (e.g., *blurk*) (e.g., Bowers, 1994), or nonrepresentational line patterns and designs (e.g., Schacter, Cooper, & Delaney, 1990). Further, priming for new associations has been shown by presenting unrelated pairs of words together in a study phase (e.g., *table-pride, window-potato, mountain-pride*), and then comparing test-phase priming for identical pairs (*table-pride*) versus recombined pairs (*window-stamp*). People show greater priming for the identical than the recombined pairs, thereby demonstrating priming for a novel association between two words created by their random pairing at study (e.g., Graf & Schacter, 1985).

Priming is not a unitary memory phenomenon. Any given task invokes multiple cognitive mechanisms that drive multiple kinds of priming. For example, a functional dissociation between tasks that invoke primarily *perceptual* or *conceptual* processes in priming has been demonstrated in studies with young subjects (Blaxton, 1989). Perceptual priming tasks draw upon processes concerned with the visual, auditory, or tactual form of a target stimulus. These tasks yield priming that is maximal when stimuli are analyzed for perceptual features at study and at test, and diminished by study-test changes in perceptual features (e.g., auditory-to-visual modality and word-to-picture notation). Conceptual priming tasks draw upon processes concerned with the content or meaning of a target stimulus. These tasks yield priming that is maximal when stimuli are analyzed for conceptual features at study and test, and insensitive to study-test changes in perceptual features.

Neuropsychological and neuroimaging studies have begun to reveal the neural mechanisms supporting priming memory. Amnesic patients with focal bilateral damage to mesial-temporal and/or diencephalic structures have normal levels of priming memory for the very materials they cannot recall or recognize (Cermak, Blackford, O'Connor, & Bleich, 1988; Gabrieli et al., 1994; Graf, Squire, & Mandler, 1984; Warrington & Weiskrantz, 1968, 1970). Priming memory is also intact in patients with progressive damage to subcortical nuclei due to Parkinson's disease (without dementia; Bondi & Kaszniak, 1991) and Huntington's disease (Heindel, Salmon, Shults, Walicke, & Butters, 1989). Thus, the neural substrate supporting priming memory does not appear to include limbic, diencephalic, or subcortical circuits.

Studies of patients with Alzheimer's disease (AD) have suggested what neural substrates may underlie priming memory (Fleischman & Gabrieli, 1999). AD is characterized by degeneration of mesial-temporal structures, which, as in focal amnesia, results in profoundly impaired recall and recognition. Unlike focal amnesia, AD is additionally characterized by progressive and selective damage to association neocortices, which causes deficits in multiple cognitive domains as well as reduction or failure of some kinds of priming memory. These findings suggest that association

neocortex may be the critical neural substrate underlying priming memory.

Some kinds of priming memory remain robust in AD, and the pattern of preservation and loss in priming parallels the regional distribution of neuropathological change that occurs in the disease. Posterior cortical regions are relatively preserved early in the course of AD (e.g., Damasio, Van Hoesen, & Hyman, 1990), and so is perceptual priming (e.g., Fleischman et al., 1995; Park et al., 1998; Postle, Corkin, & Growdon, 1996), whereas anterior cortical regions are damaged in AD (e.g., Damasio, Van Hoesen, & Hyman, 1990), and conceptual priming is impaired (e.g., Monti et al., 1996; Salmon, Shimamura, Butters, & Smith, 1988). These AD findings converge with findings from neuroimaging activation studies (Blaxton et al., 1996; Buckner et al., 1995; Schacter, Alpert, Savage, Rauch, & Albert, 1996; Squire et al., 1992) and focal lesion studies (Fleischman et al., 1995; Gabrieli, Fleischman, Keane, Reminger, & Morrell, 1995; Keane, Gabrieli, Mapstone, Johnson, & Corkin, 1995) that have demonstrated a posterior cortical locus for visual perceptual priming and have implicated regions of left frontal cortex (Gabrieli, Desmond, Demb, & Wagner, 1996) and left frontal and temporal cortex (Blaxton et al., 1996) in conceptual priming.

Priming as a long-term memory phenomenon independent of conscious forms of long-term memory is a relatively recent discovery. Initial studies date back 25 to 30 years, but the most intensive research in the area has been done only in the past 10 years.

PROBABILITY

Probability theory is important to psychology because it is the foundation upon which statistics is based, and statistics are the tools for conducting empirical research. The basic notions of chance and probability have a very long history. Gambling, the throwing of dice, and randomization procedures such as the drawing of lots are very ancient, if not prehistoric. While these concepts were vague by modern standards, it is surprising that even the simplest sort of probability calculus was not invented until relatively recent times. Why this did not take place much earlier is a matter of some mystery and controversy.

Systematic work leading to a formal appreciation of probability did not begin until around 1650, when the idea of relative frequencies and the likelihood of particular events based on gathered data began to take hold. The primary motivation for the study of probability at this time (besides gaming) was the establishment of actuarial tables based on local death records, initially compiled to keep track of the progress of the plague afflicting London late in the sixteenth century. In a sense, the origin of modern statistics and probability theory can be seen as a result of the plague, an idea that undoubtedly resonates with the feelings of many students beginning the study of statistics and probability!

Graunt (1620–1674) was the first to organize mortality records so as to make probabilistic inferences based on actual proportions and relative frequencies of events. For example, he argued in reasonably modern terms that one need not fear dying insane ("a Lunatick in Bedlam") because the odds against it were quite high (about 1500 to 1). About the same time, the analysis of "games of chance" provided the basis for further development of probability theory in the work of Pascal (1623–1662), Fermat (1601–1665), Huygens (1629–1695), and Bernoulli (1654–1705). This work saw the first development of a true mathematical foundation or theory of probability.

Early in the eighteenth century work on the binomial distribution was begun by Bernoulli and continued later by de Moivre (1667–1754). Bernoulli also developed the theorem that eventually became known as the "Law of Large Numbers," probably one of the most important events in the development of probability theory as it relates to statistical testing. The work of Laplace (1749–1827), a French astronomer and mathematician, was also significant. His two main treatises on the theory of probability and the "laws of chance," published in 1812 and 1814, provided the foundation upon which probability theory is based. This work led eventually to the development of the method of least squares, the law of errors, and the normal distribution by Laplace, Gauss (1777–1855), and others early in the nineteenth century.

One of the first practical applications of this work was in astronomy. The general problem was the necessity of fitting observations to theoretical distributions so as to be able to reject discrepant observations, not unlike many modern applications in the behavioral sciences. When astronomers became concerned with errors of measurement early in the nineteenth century they eagerly seized upon the work of Gauss. The oldest of the "exact" sciences, it is perhaps ironic that astronomy was the first to systematically apply the principles of probability. Particularly interested in the work of Gauss was the Prussian astronomer Bessel (1784–1846), who in 1818 devised the concept of the "probable error," a precursor of the standard error and comparable, in modern terms, to a 50% confidence interval. Thus many of the ingredients necessary for the development of statistical tests and statistical inference—probabilistic inference, distribution theory, methods of least squares, and the probable error—were all present before 1850.

Extension of the use of the probable error from astronomy to the biological and social sciences was first proposed by the Belgian astronomer and mathematician Quetelet (1796–1874). Before Quetelet, it is fair to say that the word *statistics* retained its original meaning, referring primarily

to descriptive data about the state, or "political arithmetic." Quetelet was the first to envision the utility of combining statistics with probability theory to develop a social science based on the Law of Large Numbers. The most famous example of Quetelet's work was his description of the frequency distribution of the heights of 100,000 French army conscripts. He noted that the distribution closely followed the normal curve, and he computed its probable error. Using this information, Quetelet calculated the number of conscripts expected in each height category and compared these to the observed numbers. He found the number of conscripts in the lowest category, just below the minimum height requirement, considerably exceeded the expected number, while the frequency in the category just above the cutoff was deficient by the same amount. He ascribed the discrepancy to fraud, asserting that such an occurrence could not have arisen through measurement error.

Quetelet's work greatly influenced the subsequent work of Galton (1822–1911), and through Galton, had great impact on the founders of modern statistics early in the twentieth century, including Karl Pearson (1857–1936) and Fisher (1890–1962). The influence of Quetelet's work was substantial because it was the first to present the principles of probability in terms accessible to nonmathematicians and to suggest specific applications for probability theory beyond the evaluation of measurement error in the physical sciences. Quetelet expounded the view that social phenomena were subject to quantitative laws just as physical phenomena obeyed the laws of Newton and Kepler. He believed that the fusion of statistics and probability could reveal the underlying laws of nature governing human behavior, leading ultimately to his concept of *l'homme moyen,* the average man. Such a view nicely fit the mechanistic philosophy that resulted from the scientific revolution of the seventeenth century, the legacy of Newton and Descartes. Ironically, this philosophy was soon demolished in the physical sciences by the quantum revolution, but it became the dominant force in the developing science of human behavior and remains so today.

PROPAGANDA

Propaganda is the advancement of a position or view in a manner that attempts to persuade rather than to present a balanced overview. Propaganda often carries the connotation of a government activity, although persuasive communications are, of course, regularly used in the private or voluntary sector.

In marketing products or services, public relations and advertising activities represent a form of propaganda, since they are not necessarily interested in communicating the whole truth, but in selective communication of information for the purpose of encouraging sales.

In the United States, one popular use of the concept of propaganda is to describe persuasive communications with which we are not in sympathy. If someone else does it, it might be described as propaganda, with negative connotations. If we do it, the communication will be designated in some other way. Thus, the official vehicle for American overseas propaganda in World War I was called the Committee on Public Information.

Propaganda, seeking to effect attitude change, can be contrasted with education, which seeks to communicate knowledge. The study of propaganda can be regarded as a branch of several larger fields, such as mass communication, mass persuasion, attitude change, and psychological warfare.

Propaganda use increases in wartime, as one indirect method of fighting the war. In a war situation, "white" propaganda identifies its source, "gray" propaganda gives no source, and "black" propaganda attributes the material to a source other than the one that actually produced it. The first systemic study of wartime propaganda was conducted after World War I by H. D. Lasswell. He studied each side's success in achieving four objectives: demoralizing the enemy, mobilizing hatred against the enemy, maintaining the friendship of neutrals, and possibly obtaining their cooperation. The British were probably most successful in associating themselves with humanitarian war aims. Lasswell demonstrated that it is more productive to analyze propaganda in terms of content categories than in terms of presumed effects because of difficulty in measuring effects.

In military propaganda, which seeks to subvert the morale of an enemy, the target is the potential waverer, who is still fighting but has lost any enthusiasm. To expect such persons to surrender on the basis of propaganda is unrealistic, but they might be encouraged to permit themselves to be captured, under appropriate circumstances.

Between World Wars I and II in the totalitarian countries, propaganda was used quite openly and nonevaluatively as a descriptor, so that Josef Goebbels in Hitler's Germany was proudly identified as the head of the country's Propaganda Bureau. America has generally described its agencies that do comparable work as engaging in "information" or "communication" activities. In the United States, propaganda has carried negative loading especially since the 1930s, when it was identified with the efforts of Germany and Italy to obtain favorable views of their new political organizations. Indeed, for many years after World War II, the content of American propaganda communication overseas was not available in this country, for fear that it could be used for domestic political purposes.

The Institute for Propaganda Analysis was established before World War II in New York City by a number of aca-

demic scholars for the purpose of educating the general public in the techniques employed by the fascist countries in their proselytizing activities. Systemic content analysis was used by the Institute in its efforts to inform the American public about the menace of fascist propaganda. In addition, the Institute defined 11 propaganda techniques: selecting the issue, stacking the cards, simplification, name calling, glittering generalities, transfer, testimonials, plain folks, bandwagon, hot potato, and stalling. The scholars of the Institute believed that by identifying the mechanisms of foreign propaganda, its ability to influence Americans would be undercut.

During World War II, systematic content analyses were conducted of the writings and other communications of native fascist groups and of German Nazi output. A comparison of these two kinds of content, admitted as evidence in court, contributed to the conviction of some native fascist groups in federal trials for the crime of sedition. Other publications and radio stations were cleared of the charge, using similar content analysis techniques as evidence.

The intensive American studies of propaganda approaches during World War II, the results of which were used to indoctrinate our military personnel with film series like "Why We Fight," led to major subsequent research programs in psychology departments at Yale and other universities. These programs conducted basic research on the formation and modification of attitudes and the role of personality characteristics, such as influenceability.

It is possible that influenceability or persuasibility by propaganda and other persuasive communications is a general trait, but research on the subject has had only moderate success in identifying its correlates. Propaganda is most likely to be effective with people who are already in favor of the views it is promoting. If they are not in favor, they may not expose themselves to it. If they are not in favor, but are exposed to it, they may not comprehend the message because they fail to identify with it or because they change its frame of reference.

One avenue in the study of propaganda involves the analysis of fear appeals in persuasion. Dependent variables studied include such issues as drivers' intention to use seat belts and parents' willingness to obtain appropriate inoculations against disease for their children. Although the results are not consistent, there is an overall tendency in producing attitude change from propaganda for a positive relationship between the intensity of fear arousal and the amount of attitude change that subsequently occurs.

In the study of political propaganda, it may be useful to measure the amount and kinds of emotionalization, often by counting the incidence of emotionalized words or concepts. Another approach involves measuring the different kinds of sources for assertions and claims, in terms of the prestige and social status of the persons to whom a viewpoint is attributed.

The rapid expansion of the Internet at the end of the twentieth century led to considerable fear that it would become a significant vehicle for the efficient spreading of various kinds of undesirable or antisocial propaganda, especially among young people. This seems unlikely for at least three reasons: (1) The Internet's system of routers minimizes communicators' secrecy and facilitates tracking message sources; (2) It is relatively easy to put up a new web site to contradict another site's messages; and (3) Internet clutter interferes with messages being received and absorbed.

In addition, many young people who grew up with the Internet were familiar with the revelations generated by Watergate, the Vietnam War, the Cold War, and the savings and loan and corporate accounting scandals around the turn of the century. These revelations help to reinforce cynicism about the integrity and motivations of some of the major institutions that disseminate propaganda. Even without the Internet, however, propaganda will continue to be important as long as there is competition between nations, political parties, and marketers, and in other adversarial situations in which communication is a tool.

PROSOCIAL BEHAVIOR

Prosocial behavior has traditionally been defined as responses that have no obvious benefits for the responder, but are beneficial to the recipient (i.e., actions that benefit another person without any expected reward for the self). A significant number of studies have found evidence of concern for others beginning in infancy and developing throughout childhood and adolescence. Girls have generally been thought to be (or capable of being) more prosocial than boys; however, the majority of research has not found appreciable gender differences in prosocial behavior. Both internal and external mechanisms have been proposed as determinants of prosocial behavior.

The family and caretaker milieu have been suggested to be critical contributors as models and sources of specific standards of prosocial behavior. Parents and caretakers of children who exhibit prosocial behavior are typically prosocial in their own actions and seek to promote such actions. For example, they point out models of prosocial behavior and direct children toward stories, television programs, movies, and videos that illustrate cooperation, sharing, and empathy and encourage generosity, helpfulness, and sympathy. These significant adults also employ inductive disciplinary methods as opposed to power-assertive practices. Interactions with siblings and peers also provide opportunities for trying out caring behavior and learning to see oth-

ers' points of view, as well as offering models and reinforcers of prosocial behavior.

From middle childhood through adolescence, cognitive development relative to perspective taking—the capacity to imagine what others may be thinking and feeling—increases the potential to act prosocially. While perspective taking can vary greatly among children and adolescents of the same age, cognitive maturity as well as interactions with adults and peers who explain their viewpoints and emotional experiences encourage noticing another's perspective. Interactions that provide practice in perspective taking have been shown to increase empathy and promote prosocial responding.

Motives for prosocial behavior change with the development of more mature moral reasoning. Young children tend to exhibit egocentric motives, such as the desire to earn praise and avoid disapproval. They weigh the benefits and costs to themselves and consider how they would like others to behave towards them. As moral reasoning develops, children become less self-centered and adopt societal standards of "being good" which eventually become internalized in the form of higher-level principles and values.

As individuals mature, they understand more, are better able to grasp the consequences of their behavior, and learn to accept and act upon general principles of morality. Cultures vary in the extent to which they foster prosocial behavior. Traditional collectivist cultures tend to inculcate prosocial values more than cultures that emphasize competition and individual achievement. External emphases have focused on situational determinants of prosocial behavior. Two major theoretical approaches for understanding prosocial behavior have stressed the importance of the situation or setting: a reinforcement explanation of why persons sometimes help others, and a cognitive analysis of the manner in which perceptions and judgments can influence behavior. From the point of view of some learning theorists, prosocial responses occur because they have been rewarded in the past. In addition to direct experiences, individuals are also influenced by their expectations about future rewards or punishments.

Among factors found to affect prosocial behavior are external determinants such as the presence of bystanders. The presence of more than one bystander in an emergency situation tends to inhibit the responses of each person present. This bystander inhibition appears to be a function of individuals' uncertainty about the situation. People respond less when circumstances are ambiguous, when they are unfamiliar with the surroundings, and when they are unsure of the behavioral norms of a particular setting.

Internal factors found to affect prosocial behavior include such variables as the mood a person is experiencing. Helping behavior increases when individuals are in a positive mood. Prosocial behaviors enhance and prolong an already positive mood; positive moods promote thinking about the rewarding nature of prosocial behavior. While prosocial behavior can offer a means to escape a negative mood, negative moods tend to encourage greater self-focus and thus decreased attention to others. Prosocial behavior also varies as a function of the relative balance of perceived costs and perceived rewards.

PSEUDODEMENTIA

The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (*DSM-IV*) describes dementia as an organic mental syndrome characterized by global impairment in memory severe enough to interfere with the ability to work or severe enough to interfere with the ability to carry out social activities. Memory loss in dementia can be associated with faulty judgment, a tendency to avoid new tasks, and problems with impulse control. Friends and family may also note personality changes. The *DSM-IV* generally assumes that dementia has an underlying organic cause.

For dementia to be diagnosed, there must be evidence of impairment in short-term as well as long-term memory. In addition, one of the following must be present: (1) impairment in abstract thinking as noted, for example, by impaired performance in such tasks as defining words and concepts and finding similarities and differences in related words; (2) impaired judgment; (3) other impairments of higher cortical functioning, which can include problems in carrying out language or motor functions; or (4) changes in personality.

If no findings point to an organic basis for dementia, the manual advises that an organic cause can still be assumed if no other factors can be found as causative agents. *Pseudodementia* refers to nonorganic factors that can account for symptoms of dementia. Initially, this condition was

named depressive pseudodementia under the assumption that depression will cause cognitive symptoms, including memory impairments. Andrew A. Swihart and Francis J. Pirozzolo (1988) pointed out that pseudodementia as a diagnostic category is not clearly defined, explaining that characteristic features of pseudodementia include reversibility of memory and other intellectual impairments once the nonorganic disorder has been accurately diagnosed and treated. In contrast, dementia is not reversible and is usually progressive even though there may be long, plateaulike periods.

Most often, pseudodementia occurs in individuals over the age of 50, although it can occur at any age. Asenath LaRue, Connie Dessonville, and Lissy F. Jarvik (1985) noted that 30% of individuals diagnosed with pseudodementia may be incorrectly classified. Some individuals tend to improve without treatment, whereas others respond to treatment for depression. Although it is often difficult to apply clinical criteria to differentiate between demented and depressed individuals, there have been a number of attempts to do so. Memory loss for recent events is about the same as for distant events (demented patients often have greater memory loss for recent events). Pseudodemented patients' emotional reactions (coping, affective state, concern about disability, and general complaints) tend to be emphasized in contrast to demented patients, and previous psychological problems are more frequently reported, though the ability to concentrate may be relatively intact. Overall, performance on neuropsychological assessment tasks may be more variable, with a greater likelihood of "don't know" answers as opposed to "near misses." Most authorities agree that pseudodementia is especially difficult to diagnose. Furthermore, this diagnosis has not been demonstrated to be conclusive and is often based more on an overall pattern of diagnostic signs and the overall clinical history of the patient other than on specifically pertinent symptom constellations.

The previously cited authors (LaRue, Dessonville, & Jarvik, 1985) suggested that pseudodementia represents a consciousness-raising diagnosis that encourages health service providers to be cautious in making a diagnosis of dementia, because this often results in termination of active treatment attempts. Andrew Swihart and Francis J. Pirozzolo (1988) pointed out that just because dementia is eventually irreversible, efforts at treating demented patients should not cease.

Steven Zarit and Judy Zarit (1998) discuss pseudodementia under the rubric of the association of dementia and depression. They, along with other authorities, suggest that it is not accurate to assume that pseudodementia is reversible, though it is always important to evaluate potential reversible elements. Sergio Starkstein and Robert Robinson (1993) emphasize the impact of depression on cognitive functioning and go on to speculate that perhaps there is a different mechanism operating for patients with left-side brain lesions as opposed to right-side lesions. They found that patients with right hemisphere lesions with depression do not show the same cognitive impairments as do patients with left hemisphere lesions.
